### Scientific Worthies.

XLV -- RICHARD WILLSTÄTTER.

"For all flesh is as grass"—1 Peter i. 24.

"A child said, What is the grass? fetching it to me

with full hands; How could I answer the child? I do not know

what it is any more than he. I guess it must be the flag of my disposition, out

of hopeful green stuff woven.

"Or I guess the grass is itself a child, the produced babe of the vegetation.

Or I guess it is a uniform hieroglyphic

And it means, Sprouting alike in broad and narrow zones.

"And now it seems to me the beautiful uncut hair of graves."

WALT WHITMAN, Leaves of Grass.

HEMISTRY is both a craft and an art, one of the finest of arts-perhaps the art of arts, a veritable "sword of Aklis," wherewith the threads are cut which hold the secrets of our material world and the nature and character of its component units disclosed; it has a wondrous psychology of which but few as yet have gained feeling, mastery and reverence. A science only in the second degree, because so much of its burden cannot be quantified, chemistry is none the less a premier science, through the exquisite finish of the enviable craftsmanship exercised by the men of genius who have been successful in its service. Among the craftsmen who have most adorned our ranks, we can place none higher than the subject of this memoir, for he has reached to the highest pinnacle of technical proficiency to which our art has been carried. A striking

feature in his conquests has been the sureness and swiftness of his approach, the courage of his attack and his deft handling of situations which previous workers have failed to master.

A biographer writes · 1 " It is an open secret to the few who know it but a mystery and a stumbling block to the many, that Science and Poetry are twin sisters: insomuch that in those branches of scientific inquiry which are most abstract, most formal and most remote from the grasp of the ordinary sensible imagination, a higher power of imagination akin to the creative instinct of the poet is most needed and most fruitful of lasting work "

The chemist who can teach so much of grass, who can go so far towards answering the question put by the child to which the poet confessedly had no answer, who can also lay bare the secret of colour in flowers, may be placed even above the poet. The poet but deals with the superficial and with fancies; at best he is a mere painter. The full beauty of Nature, the structure of her wondrous mechanism, is patent only to the chemist: he is fast learning to interpret her 'uniform hieroglyphie' in terms which admit of no dispute. Now that we can think in terms of the Ångström unit, our vision is become ultramicroscopie. Our science of chemistry, in fact, is no twin sister of poetry but poetry itself and at its highest. Its mysteries are as deserving of attention and as marvellous as are those of even the densest stars. Indeed, the saga of the universe is before us in grass, if we will but read it: we know that "all flesh is as grass." The alphabet in which the story is told, in reality, is one of remarkable simplicity and that so few care to make the attempt to master our shorthand, the language in which our story of flowers is told, is surprising, to say the least. The outward beauty of the flower is patent to every one—the inward beauty of its mechanism, to the seeing eve, is marvellous beyond compare—the man who has done so much to interpret its character may well be deemed worthy among us.

Richard Willstätter was born in Carlsruhe (Baden) on Aug. 13, 1872. At first, he was educated there but afterwards, on removal of his parents to Nürnberg, at the Realgymnasium of that town. When eighteen years old, he entered the University of Munich, where he began the study of chemistry under the great Adolf von

No. 3009, Vol. 1207

Bacyer, a master of laboratory eraft, known to the world as the first to prepare indigotin artificially, the colouring matter of the indigo plant. The fifteen years of his career were spent there as student and privat-docent, and finally, from 1902 onwards, as extraordinary professor and head of the organic chemical department. In the spring of 1902, he was appointed full professor (ordinarius) at the noted Zürich Technical High School. After spending seven years in Zürich, in 1912 he returned to Germany to take charge of the Chemical Research Department established by the Kaiser Wilhelm Society at Dahlem, Berlin. It was here that he carried out most of his work on plant-colouring matters. Ultimately, he be came professor at Munich, in succession to Adolf von Baeyer. He was elected a member of the Prussian Royal Academy of Sciences in 1915 and received the Nobel Prize in 1920.

It appears to have been Willstatter's ambition, from an early stage in his career, to undertake the study of vegetable and animal pigments and he advisedly entered upon a considered course of original study to acquire the necessary technical proficiency in preparation for this task. Beginning with the vegetable alkaloids, atropine and cocaine, which he was able to prepare artificially, he passed to the study of the quinones, a class of compound to which at least a majority of dyestuffs belong. He made a notable addition to knowledge by his discovery of orthobenzoquinone. He then entered upon his great inquiry into the nature of chlorophyll. He next devoted himself to the study of the red and blue colouring matters of flower: Of late years he has been engaged in the attempt to isolate enzymes. These, however, are only the main lines of inquiry which have occupied his attention. A German professor, especially if he be a man of established repute, is called upon to provide subjects for a large body of young workers. hence it comes that Willstätter has touched a great variety of themes other than those referred to above. He has thus been led to solve a number of problems of special interest and more than ordinary difficulty. Among the inquiries, that on hydrogenation under the influence of platinum may be referred to as one of prime importance.

The studies of the green colouring matter of plants are described in twenty-four memoirs, published in Liebig's Annalen der Chemie during the years 1906-14, and in a book written in conjunction with A. Stoll (Berlin, 1913). It will be remembered of Shibili Bagara that he "pre-

<sup>&</sup>lt;sup>1</sup> F. Pollock in Leslie Stephen and Frederick Pollock's Lectures and Essays, by W. K. Clifford.

pared a rapid lather and dashed it over Shagnat and commenced shaving him with lightning sweeps of the blade (Aklis). 'Twas as a racing wheel of fire to see him." So Willstatter with chlorophyll. When he began the inquiry, the view prevailed that chlorophyll was but a group name and even that each plant might contain its specific chlorophyll. Not the least remarkable outcome of his work has been to show that, in more than two hundred species of Cryptogamic and Phanerogamic plants, the same mixture is to be found, in slightly different proportions, of two closely related compounds, which he has termed  $\alpha$ -chlorophyll and  $\beta$ -chlorophyll, the former being blue-green, the latter yellow-green This result is surprising in view of the fact that no two animals contain the same hæmoglobin, although one hæmatın is common to all, the globin (protein) component varying from species to species Willstatter has further shown that, in the cell plastid, as indeed Sir G G Stokes first pointed out in 1864, the two chlorophylls are associated with two 'yellow' colouring matters, one the well-known hydrocarbon carotene, C40H56, the other a previously unisolated compound, xanthophyll, C<sub>40</sub>H<sub>56</sub>O<sub>2</sub>, apparently a derivative of carotene The Phæophyceæ alone also contain a third carotinoid, fucoxanthin, C40H56O6

The method of separating the chlorophyll compounds adopted by Willstatter is that originally proposed by Stokes and involves the use of more or less immiscible solvents, particularly petroleum spirit and aqueous alcohol. Being soluble in a mixture of petrol and alcohol but insoluble in petrol,  $\alpha$ - and  $\beta$ -chlorophyll are precipitated when the alcohol is washed out of the solution. The method is one by means of which the pigments may be extracted from either dry or fresh leaves as easily as may an alkaloid or a sugar. The two chlorophylls are separated by fractional crystallisation from methylic alcohol and petrol. They are usually present in the proportion of about three molecules of the a- to one of the  $\beta$ -compound. Their composition is remarkable, that of the a-compound being represented by the formula

### $C_{32}H_{30}ON_4Mg(CO_2CH_3)(CO_2C_{20}H_{39}).$

The  $\beta$ -compound differs only in containing an additional atom of oxygen. It will be seen that they are dicarboxylic derivatives. Significant constituents are magnesium and the radicle  $C_{20}H_{39}$  of the complex alcohol, *phytol*,  $C_{20}H_{39}$ . OH, about one-third of the weight of the molecule consisting of this component. The condition of the magnesium

is peculiar, as the metal is not displaced by the action of alkalies, though readily by that of acids. Its behaviour, therefore, is similar to that of the iron in hæmoglobin. The carboxyl-free mother substance of  $\alpha$ -chlorophyll is a complex pyrrole derivative ( $\alpha$ -chlorophyrin) and the magnesium is probably associated with the nitrogen in this complex. This derivative is represented provisionally by the formula

Ætioporphyrin is a compound of outstanding interest as it is also obtainable from hæmoglobin. It is noteworthy that Fischer and Klarer have recently prepared a compound synthetically from 2:4-dimethyl-3-ethylpyrrole which appears to have the properties of Willstatter's product. That primary functions of life should be exercised, both in the plant and in the animal, by compounds of similar parentage is more than remarkable function of hæmoglobin, apparently, is that of a mere oxygen carrier—it is little more than a gasholder. Chlorophyll plays a far more complex part, as it in some ways promotes the absorption of solar energy that is involved in the reduction of carbonic acid to formaldehydrol, CH<sub>2</sub>(OH)<sub>2</sub>, and the concurrent elimination of oxygen, in the primary process of assimilation.

Willstatter and his co-workers have shown that the chlorophylls remain unaltered in amount throughout the process and that they can enter into loose conjunction with carbonic acid: possibly the connexion is established through the magnesium and the carbonic acid thus made part of the energy-absorbing system. Once formaldehydrol is produced, passage to the sugars is a simple matter: yet this must be a directed operation, as the aldehydrol gives rise to only one of the two optically opposite forms of hexose. Those who talk glibly of the artificial imitation of the life process forget these little peculiarities and limitations—and so mislead the public into unjustifiable

beliefs. Whatever the process, there is no reason to believe that earbonic acid is more than half reduced and the oxygen that is liberated is probably not derived from the earbon dioxide but is formed by the electrolysis of water. The operations are carried on within the chlorophyll plastid in presence of carotene and xanthophyll, both highly oxidisable substances; it is surprising that oxygen should be liberated within such a system and be without effect upon it, the more as various oxidisable materials are formed within the plastid. Elsewhere, I have ventured to suggest, that the yellows serve to inhibit oxidation and thus exercise a protecting effect upon the system an effect such as Moureu and Dufraisse have shown to be often produced by the 'interference' of substances which are oxidisable separately but in admixture, apparently, are unaffected by oxygen.

The statement is made in Sir Frederick Keeble's recent work on "The Life of Plants" that

"The wheat plant alone, producing as it does a world crop containing some 70 million tons of carbohydrate, 'handles' each year about 114 million tons of carbon dioxide and liberates to the atmosphere over 80 million tons of oxygen. The energy-value to the plant of the carbohydrate produced during photosynthesis may be computed on the basis of the amount of heat found by experiment to be liberated when a given amount of starch is caused to undergo combustion. The combustion of one ounce of starch liberates 116 calories and it is, therefore, only a matter of calculation to discover the energy value in terms of calories of the carbohydrates of the world's wheat-crop. The heat which would be produced by the combustion of the 70 million tons of carbohydrate would suffice to raise to boilingpoint all the water of an ice-cold lake four miles long, four broad and of an average depth of forty fathoms."

As all plants, through their leaves, exercise a similar activity, chlorophyll does some work in the world—we, therefore, might well learn to look upon it with respect, even take some little interest in its character and functions.

Of what value, however, is colour in the flower? Who shall say what the significance of colour may be? We are most of us alive to its æsthetic charm and value—what of insects: are they? If attracted by it and the fertilisation process be in large measure an outcome of such attraction, then indeed it is of utmost consequence to life.

The patterns of the colours in flowers have been deciphered with surprising skill and surprising swiftness by Willstätter and he has shown, more-

over, that they are of remarkable simplicity. He has dealt with the reds and blues, which he has termed anthocyans, the yellows have been fairly well studied by others. In many plants, yellow and orange are due to xanthophyll and carotene: in other cases, they are mostly traceable to the presence of hydroxy-derivatives of flavone, present as a white meal upon the leaves and flower stalks of many of the Primulaceae. Flavone, as shown by Hugo Müller, may be resolved into acetophenone and salicylic acid—two simple substances.

The anthocyans are mostly glucosides, yielding on hydrolysis either glucose or galactose or rhamnose together with the coloured component or anthocyanidin, which in some cases is a methylated derivative. They are resolved by the action of alkali into the trihydroxybenzene, phloroglucinol, either parahydroxybenzoic, protocatechuic acid or gallic acid or maybe a methylated derivative of one of these. The parent substance may be formulated as an orthoguinonoid derivative,

In many respects their properties are peculiar but it is impossible to discuss them here. The reds are but acid forms of the blues. As in the flavones, the intensity of the colour increases with the number of hydroxy groups in the lateral phenyl group. Much might be said on the relation of colour to structure in these compounds were space available—no more fascinating subject could be entered upon.

Willstätter's work has of course been followed by a synthetic repercussion. In recent years, Prof. Robinson, in Manchester, has most skilfully developed methods with the aid of which it is possible to prepare anthocyanidins in the laboratory in any desired quantity: so to-day we can paint the lily with its own pigments.

Passing now to Willstätter's most recent work, that on enzymes, we are brought into a troubled field, one which, however, we must contemplate

No. 3009, Vol. 1201

with wonder, as their activities lie behind the mysteries of life.

\*The colouring matters of plants appear to be without functional significance—they seem to be mere dress effects. Chlorophyll, however, is life at its outset, as by its agency the bricks are shapen which Nature hands to the plant: not only so, for with its aid energy is captured from the sun, which the plant not only uses to its own ends but also passes on to us. What of the enzymes, Willstätter's latest subject of study? Life, we know, in the main involves only two processeson one hand, that of hydrolysis and its reverse; on the other, that of oxidation (hydroxylation) and its reverse. Oxidation, apparently, is determined and controlled by agents which are limited in their range of action but not specifically selective and, therefore, are not to be counted with the enzymes. The enzymes are the agents in charge of the hydrolytic process, whether this be downgrade or upgrade. They apparently are the templates which regulate constructive metabolism, both in plants and animals, for they are strictly selective agents. Hitherto they have been elusive entities, only characterised by their effects Willstatter's efforts have been to prepare them in the individual state, so that they may be further characterised and their nature determined. The task is one of extraordinary difficulty. He has shown that they may be handled with far greater impunity than had been supposed and has devised methods of purifying them whereby he has greatly raised their activity but without arriving at any definite result. The final picture he has drawn for us of the enzyme is that of a colloid carrier of a group which is the active component: a picture drawn by my son and myself in 1913; indeed, we went further, in showing the colloid in attachment with a directing group, in addition.

I perhaps more than any one can appreciate the value of work so varied yet always in logical connexion—can wonder at the genius displayed and the self-sacrificing devotion of the worker to his task. Only the few among us can be aware what such inquiry means, what it involves -what are its joys-what its pains. Perhaps, some day, these matters will come home, in some slight measure, to those who in the arrogance of their ignorance pretend to rule the world-I say this because I should like to think that "the flag of my disposition [is] out of hopeful green stuff woven" and that the moral value of inquiries such as have been referred to may not always remain unknown HENRY E. ARMSTRONG. to the public.

Corrosion-Some Causes and Remedies.

The Corrosion of Metals. By Ulick R Evans. Second edition. Pp. xv1 + 259. (London: Edward Arnold and Co, 1926) 15s net

TWO years ago (May 23, 1925, p 793) the first edition of Mr. Evans's book was reviewed by the present writer in the columns of NATURE. Its good qualities have evidently been widely recognised, since a second edition has recently been published. The author states in his preface to this that progress made during this period in the understanding of the processes of corrosion has made so many additions necessary, that it has taken him longer to write the second edition than the first. The same general arrangement has been preserved, and he has adhered to the policy of giving a concise statement of the subject in the text accompanied by numerous references in the foot-notes to papers where further details can be sought on any particular point of interest. The net result is the production of a book some forty pages longer than the original volume and the published price has been slightly increased.

We learn from the chapter on the corrosion of copper and copper alloys, that an interesting protection process has recently been adopted by the Cunard Steamship Company, Ltd, which consists in spraying the interior of the condenser tubes with a bituminous composition. Austin, who has described the process in detail (Trans. Liverpool Eng. Soc., 46, 1925), states that the vacuum is reduced by ½ to ½ inch (owing to the decrease in the thermal conductivity of the coated tubes) but the over-all efficiency is not affected. Mr. Evans suggests as the reason for this, the increased cleanliness of the boiler heating surfaces and turbine blades. So far the experiment has proved very successful, only 21 tubes out of 28,500 having failed since its installation. As yet the process has not been tested in ships sailing in warm waters. The electrochemical process for protecting condenser tubes is stated to be somewhat of a disappointment, and the latest reports from many trustworthy sources indicate that in many cases little or no benefit has been obtained where it had been installed. Dr. Honegger states that in some cases the process has failed completely, while in other cases it has proved very useful It seems quite possible that in the latter cases this has been achieved by the deposition on the tubes of a film of 1ron compounds derived from the anode rather than by true cathodic protection. Bengough and Stuart have pointed out that the weak feature of the method lies in the impossibility of securing the distribution of the current over the whole of the tube surface. Mr Evans directs attention in a foot-note to the fact that there is no fundamental reason why cathodic treatment should put a stop to corrosion and that cases are known where mild cathodic polarisation—by keeping the metal active—may actually accelerate attack.

In Chapter xi, entitled "Protection against Corrosion," we notice the statement that "the employment of sodium silicate (water glass) as an inhibitor is increasing." It finds application as an addition to plumbo-solvent waters prior to their entry into lead pipes. It is used in cleaning alumin-1um Both in liquid and solid form it is also being used to prevent the destruction of iron pipes by water and, in many cases, has been found to reduce corrosion considerably In recent years the same material has been used in increasing quantities in boilers. Here, however, other questions are raised, e.g. the possible effect of the protective film (which is probably silica or a silicate) on the heat-transfer, the possible increase of foaming and the action on Further research on all these the brass fittings points would be of value Hall, who has made a long study of boiler scales, points out that a calcium silicate scale has a most pernicious effect in a boiler. It is therefore not advisable to add sodium silicate to a hard water rich in calcium.

It is interesting to notice the author's statement that the electro-deposition of chromium as a protective coating is now being utilised. This metal does not adhere well to steel if deposited directly, but satisfactory results have been obtained if a thin layer of copper or nickel is first deposited on it. The chromium plating then follows, usually from a bath containing chromic acid and chromium sulphate, which must be kept cool. It is stated that plated articles manufactured in this way withstand corrosion by sea water, and also exhibit resistance to tarnishing The hardness of chromium is a considerable additional advantage. It may be that this metal will prove a serious rival to nickel in spite of the greater expense involved. Later on in the same chapter we observe a reference to the operation known in Germany as Nitrierung, which consists in protecting iron by heating it in ammonia, a process which produces a very hard nitride layer. Actually this process is mainly applied for increasing hardness, but it does afford some protection against corrosion.

Several processes have been worked out for producing protective coats upon metals by subjecting them to anodic treatment in suitable solutions.

Special reference should be made to the work of Bengough and Stuart, who have devised a method for the protection of aluminium and its light alloys such as duralumin which has given most promising results. The articles in question are made the anodes m a 3 per cent solution of chromic acid at about 40° C. The cathode consists of carbon. The applied E.M F is gradually raised to a value depending on the nature of the alloy and the composition of the bath. After treating for some time in this manner the surface of the metal becomes covered with a semi-opaque uniform white This seems to consist almost entirely of aluminium hydroxide in a glassy adherent form. Possibly it is hydrated to some extent, but the amount of hydration cannot be large, since the coating can be heated to 350° C, without changing in appearance or density. Not only does this coating afford considerable resistance to corrosion, but it also acts as an excellent basis for the application of protective paints or varnishes which are not very satisfactory if applied to untreated aluminium. The anodic protection of duralumin is finding wide application both in the aircraft industry and in the protection of artificial limbs against corrosion

The final chapter on corrosion-resisting materials contains the latest information on the many varieties of stainless steel and stainless iron now available. The alloy manufactured in England under the name of 'Staybrite' contains no less than 18 per cent, chromium and 8 per cent, of nickel; the German material known as V2A contains from 20 to 25 per cent of chromium and 6 per cent. of nickel. Unlike ordinary stainless steel, which has a duplex structure, these alloys, as Mr. Evans points out, consist of a single phase The iron is in the austenite (gamma iron) condition. Accordingly the materials are ductile and can be wrought into almost any form. It has even been found possible to weld them. Reference may also be made to stellite, which is the most important corrosion-resisting alloy of cobalt. It is a very composite alloy containing considerable quantities of cobalt, chromium, and tungsten, and smaller quantities of iron, carbon, and possibly silicon and manganese. It combines good anti-corrosion properties with great mechanical hardness.

In conclusion, it may be stated that the second edition of Mr. Evans's book is even more serviceable than the original volume, and the demand for it will probably be at least as great. We hope it will be even greater.

### A Projected Art of Light.

Colour-Music: the Art of Light By Adrian Bernard Klein. Pp. xvi + 287 + 24 plates (London. Crosby Lockwood and Son, 1926.) 36s net.

THE project of an art of light, analogous to music, threatens to become an obsession, recurring in every generation, attacking indiscriminately philosopher, artist, and empirical scientist. It is particularly insidious because it cannot be flatly dismissed as a mere chimera. There may be something in it, and there is no alternative but to think the matter out.

Other than Major Klein probably no one has combined so firm a belief in the possibility of this art with so comprehensive a group of the relevant scientific data, or with so frank a recognition of the difficulties in the way. His work will certainly rank for a long time as the standard authority on the subject, and it leaves no excuse for future exponents ignoring their predecessors' errors enormous amount has gone to its compilation Approaching the question from an historical point of view, the author has studied every important contribution, examined every instrument, and canvassed every opinion. (The bibliography ranges from Aristotle to the provincial press reports on the touring colour organ.) Not every opinion is equally important, and the author would not have been blamed if he had dealt more fully with some of the central issues at the expense of some But even in the of this historical material bewildering byways of speculation he himself is critical and alert.

Theoretically, the abstract possibility of an art of light is reasonably established. Colours presented in succession can produce a definite esthetic effect. But this is obviously not enough. Pyrotechny is a sort of art of light; but what is projected is something more profound, something really comparable to music. This is a further and more difficult issue, raising a host of technical, practical, and esthetic questions

Scientific interests enter in two ways. First, adequate theoretical foundations must be secured. The physical properties of the spectrum provide a tangible starting-point, but the scales of colour must apply to every dimension of the colour octahedron (or whatever schema is ultimately adopted) and must be empirically determined with due regard to the individual variations of differential threshold, and for all the facts of colour sensitivity arising from the peculiarities of the cerebro-retinal mechanism. A technique for estab-

lishing such scales is, of course, at hand in Fechner's psycho-physical methods, but scales so established would not imply 'intervals' of the type required. On this crucial point the whole inquiry has been given an unfortunate twist by two curious phenomena which, in virtue of their peculiarity rather than their importance, have impressed the imagination of most inventors of an art of light. One of these is the psychological curiosity of synæsthesia, the other is the, after all, surprising fact that harmonious 'intervals' experienced in awareness of tones are physically paralleled by certain simple ratios between the frequencies of the vibratory stimuli. The combined effect of these two facts has been to foster a number of fruitless attempts to accompany music by synæsthetic lights or even to translate music directly into colour, and to encourage a great deal of specious but wholly unconvincing argument to establish harmonic colour scales on the basis of the ratios of the frequencies of waves of light.

It is one of the solid merits of Major Klein's work that he refuses to be ensuared in this inversion of the natural and logical order of investigation. After a careful analysis of these theories he comes unambiguously to the conclusion that the intervals of colour must be independently established. Independently established, but how? The author, it seems, is not enamoured with the method of paired comparisons, preferring to await the birth of a colour musician who will divine the laws of colour harmony by the unaided light of Nature. That would be eminently desirable, but the point is, we rather urgently require some preliminary evidence that the laws are there for him to divine. What we know at present with regard to the harmony of co-presented colours cannot (owing to the factor of spatial configuration) be applied simpliciter to colour sequences The fact that no adequate research has been directed upon the problem of colour 'melody' constitutes a serious weakness in the theoretical foundations of this art.

A second strain of purely scientific interest enters in connexion with the provision of technical devices for the control of colour stimuli. For good, though not conclusive, reasons, Major Klein has committed himself to a policy which will engender serious practical obstacles to the cultivation and diffusion of the projected art. He requires a specially constructed hall and an elaborate type of projecting spectroscope controlled by a keyboard embodying the principles of the theoretical colour scales. Now, the art of sound has had the advantage that the human organism is itself a musical

instrument and potent instinctive tendencies have motivated its use and exercise. Per contra, the art of light lacks this natural basis—and simple instruments fail to achieve any very impressive effects. But even a tom-tom or a simple pipe can produce a distinct effect, and without them we should have had neither orchestra, composer, nor audience. Inventions of the art of light have pursued many analogies, but not the biological. What is the counterpart in colour music to the folk-song or the country dance? When his instrument is to cost £10,000, how is the colour musician to acquire facility in his art? Perhaps the failure of simple instruments points to a certain weakness in our reactions to mobile colour. The emotional possibilities may be too limited to support a vital art, and some centuries of further cultivation may be required. Perhaps, too, the author has unwittingly aggravated his difficulties by applying to a new and infantile art æsthetic theories derived from modern and sophisticated spheres. But on æsthetic theories each man may hold his own opinion, and these at any rate fall outside the scope of the present review.

The objections are not final. To prophesy a negative is as difficult as to prove one; and a new approach may completely change the situation. In any event the author has performed a useful service in presenting the problem in a clear and definite way.

C. A. MACE.

### Recent Literature on Enzymes.

- Die Fermente und ihre Wirkungen. Von Prof. Dr. Carl Oppenheimer. Nebst einem Sonderkapitel: Physikalische Chemie und Kinetik, von Dr. Richard Kuhn. Fünfte, völlig neu bearbeitete Auflage. Lieferung 9. Pp. 1205-1392. 17.40 gold marks. Lieferung 10. Pp. 1393-1568. 17.10 gold marks. Lieferung 11. Pp. 1569-1744. 17.10 gold marks Lieferung 12. Pp. 1745-1871. 17.45 gold marks. Lieferung 13. Pp. xvi+1873-2037. 19 gold marks.
- (2) Lehrbuch der Enzyme: Chemie, physikalische Chemie und Biologie. Von Prof. Dr. Carl Oppenheimer. Unter Mitarbeit von Prof. Dr. Richard Kuhn. Pp. ix + 660. 33 gold marks. (Leipzig: Georg Thieme, 1927.)
- (1) WE have already dealt with Parts 1-8 of this work, and now that it has reached completion with Part 13, including an author and subject-matter index, it seems desirable to review the entire work.

The first edition of "Die Fermente" appeared No. 3009, Vol. 1207

as quite a modest volume twenty-five years ago, and since that time the immense amount of work which has been carried out on the subject of enzymes has necessitated the publication of several fresh editions, the task culminating in the compilation of the present extensive treatise, dealing in an exhaustive manner with what is now one of the most important branches of biochemistry. The last edition of Prof. Oppenheimer's book has been out-of-print since 1918, and it was decided by the author to recast the whole work, retaining only here and there those portions of the previous text, without altering its general plan. In view of the large additions to our knowledge during the past decade, it has been found necessary to omit some of the older observations, which in the opinion of the author are obsolete. In adopting this course he points out, however, that he has paid due regard to the necessity of preserving the character of the work as giving a complete account of the subject.

We know very little at the present time concerning the chemical nature of an enzyme, but as a result of the most recent work, among which that of Willstatter stands out prominently, enzyme preparations have been purified and their activity thereby increased enormously, whilst at the same time some of them have given indications that they consist of chemical entities. But in all probability an enzyme will be found to constitute a system rather than a single chemical substance. In this connexion, however, attention may be directed to the recent work of Sumner (1926), who shows that a crystalline globulin from jack bean exhibits the activity of a urease. He states that it may be recrystallised by solution in water and addition of acetone up to 30 per cent. concentration and gradual treatment of the solution at 0" with potassium dihydrogen phosphate of pH 6·1. Here, however, we have the presence of the phosphate to be taken into account, which probably does something more than adjust the hydrogen ion concentration. What may be called the nucleal part of this system is the zymogen, which under certain conditions is rendered active. The chief of these conditions is the hydrogen ion concentration and the presence of certain electrolytes. Machaelis regards enzymes as amphoteric electrolytes or ampholytes; and this theory, developed by Bjerrum, is dealt with fully in the treatise.

The entire work is spread over 2037 pages and is divided into two volumes. The first volume, covering 775 pages of text, deals with the general chemistry of enzymes, the kinetics of their actions and the biology of the subjects, the concluding

part of the volume being devoted to the esterases (lipase, etc.), the carbohydrases, and the nucleases. The second volume is concerned with amidases, aminoacidases, proteases, and a group of enzymes connected with oxidations and reductions, to which the author has given the name desmolases, including zymase, the various oxidases and autoxidisable substances such as glutathione.

The author classifies enzymes according to the substrata on which they act thus esterases, including the lipases, carbohydrases, proteases, and desmolases, including zymases and the respiratory enzymes. He admits that if in the future some knowledge be forthcoming of the constitution of a given enzyme, a fresh classification will have to be elaborated In this connexion we may quote his remarks: "It can only be hoped that the work on the chemical nature of the ferments which Willstatter has so happily inaugurated, will lead to clear and definite results. If the structure of one of the ferments is cleared up, this will soon be extended to the whole class, just as with the hormones as exemplified in the case of adrenaline," and he might have added thryoxin, which, however, has been synthesised by Harington since the publication of this treatise.

Under physical chemistry and kinetics, ultrafiltration, kataphoresis, complexes with heavy metals, surface tension and adsorption phenomena, and reciprocal precipitation of colloids are discussed. Reaction velocity and catalysis are fully dealt with. Discussing the thermochemistry of fermentation, it is shown that the theoretical quantity of heat envolved per gram molecule of glucose fermented is  $28 \cdot 2 \, K$ , whereas Rübner found experimentally  $24 \, K$ . No reference is made, however, to the determination of the heat of fermentation of maltose by the late A. J. Brown, whose results were derived from practical data in a brewery.

The interesting observation of Kuhn (1923) is recorded that the invertase (sucrase) from yeast (bottom fermentation) and from Aspergillus oryzæ respectively behave differently towards sucrose. In the former case the hydrolysis is slackened by the presence of d-fructose, whilst in the latter case it is slackened by the presence of d-glucose.

That a treatise of so comprehensive a character as that before us was much needed, no one will deny, but much as we value it we are bound to say that the text is needlessly diffuse and abounds with repetitions. The lipase of seeds is said to be distinguished from that present in the liver and tissues of animals in being insoluble in all solvents,

and this statement is repeated several times. Many other similar cases could be cited. We are surprised to find the statement that, during germination, amylase is rendered soluble without altering its functions. Amylase of raw grain (barley) is probably partially insoluble, and the maltase which accompanies it is insoluble, but amylase of germinated grain will act on amylopectin, whereas that of raw grain merely depolymerises it.

The best way to judge a book of the kind before us, however, is to use it, and it gives the present writer pleasure to state that he has found the treatise invaluable as a book of reference on which to base his lectures on enzymes and to serve as a guide to original papers on the subject.

(2) The authors have prepared this work from the larger treatise "Die Fermente," of which it is a shortened edition, to serve as a students' manual. That such a manual was needed there can be no However, the text of the larger treatise has been to a great extent retained, the difference being that whole parts have been excised and that fewer references are given to the literature. The names of those responsible for the observations cited in the text are given in some cases without references. In our opinion it would have been much better if the work had been entirely re-cast, as it would then have been possible to reduce the size of the volume considerably and to obtain a better logical sequence in the text, which is specially desirable in a book intended for students. The subject matters are arranged in the same order as in the larger treatise, but many pieces of work which have appeared since the publication of the earlier parts of the latter are referred to, thus bringing the book up-to-date.

ARTHUR R. LING.

### Our Bookshelf.

The Reproduction of Life: a Handbook of the Science of Reproduction in Nature and Man. By A. J. Cokkinis. Pp. xvi+287. (London: Baillière, Tindall and Cox, 1926.) 10s. 6d. net.

THE author states in his preface to this book that his aim in writing it has been to fill the need of a simple, yet accurate, scientific account, intelligible to the adolescent boy or girl, of the phenomena of the reproduction of life. The problem of selection and presentation of material for a book of this kind is a difficult one, as any one who has had experience of teaching hygiene to school children will appreciate, and Mr. Cokkinis has not been very successful in solving it. He has attempted to cover an unnecessarily wide field. Those sections on plant and animal reproduction, in which he describes and figures, often inaccurately (see, for

example, Figs. 59 and 69), the reproductive organs in plants, and in the more important classes of the animal kingdom, can be studied in any elementary text-book of biology, with this advantage, that they are there set forth with correctness of detail. A short account of the cellular basis of living organisms, with a clear description of the differences between asexual and sexual reproduction, oviparous and viviparous development, would have been sufficient introduction to the study of the question in man. The great difficulty which the average individual naturally experiences in visualising, with any clearness, the position and relation of the organs of the body, makes it absolutely essential that these points should be illustrated by careful, large-scale drawings. Isolated diagrams of partially dissected systems, such as are given in this book, convey nothing to the untrained mind. H. E. B.

The Principles of Petrology: an Introduction to the Science of Rocks By Dr. (\$\frac{1}{2}\$. W Tyrrell. (London. Methuen and Co., Ltd., 1926). 10s. net.

This is the first of a geological series of books to be published under the general editorship of Prof. J W. Gregory. Two others are promised. After reading the book one feels that the author could himself have contributed three separate books on petrology. In this small volume, igneous, sedimentary, and metamorphic rocks are all dealt with, and the space is quite inadequate to the subject. The author is very widely read, as his numerous and excellent abstracts published in Science Progress prove, and he has endeavoured to include in his book every recent contribution to the science of petrology. It is indeed, to quote the author's preface, "a conspectus of the present state of the science of petrology," but it is a little doubtful whether the workers in other branches of geology or "students who have acquired an elementary knowledge of the science" will know quite how much to believe when they have read it all.

The descriptive parts of the book are very clear. Metamorphic rocks are dealt with in seven chapters describing the various processes and their products. Only six chapters can be devoted to "Secondary" rocks, classified as residual, sedimentary, and chemical. Good chapters under Part I (Igneous Rocks) describe forms and structures, and textures and microstructures. The author develops some of his own ideas on classification, and has some very interesting remarks on distribution in space and time. The suggestion to use the terms 'kindreds,' 'tribes,' and 'clans' for groups or series of rocks showing different degrees of close relationship may be useful if every one uses the terms in the same sense.

Soviet Union Year-Book, 1927. Compiled and edited by A. A. Santalov and Dr. Louis Segal. Pp. xxiii +453. (London: George Allen and Unwin, Ltd., 1927). 7s. 6d. net.

WITHIN reasonable compass this well-arranged volume gives a great deal of information about present conditions in Russian territories in Europe and Asia. The extensive bibliography of Russian works indicates that the facts and figures have been taken from the most recent official sources. No other than Russian publications find a place in the list. The agriculture, mineral resources, and trade of the Soviet Union are treated in great detail. The regulations for foreign trade are given, and particular attention is paid to the trade with Great Britain. Another section explains the policy and gives the regulations for concessions and the attraction of foreign capital to Russia. Many pages are devoted to the political organisation and the constitution of the Soviet Union, the regulations for labour, the organisation of finances, and the principal clauses of the civil code. In fact, the volume is an authoritative treatise on the country and as such is of considerable interest mainly a statement of fact, and very few expressions of opinions have crept in. There are two coloured and two black-and-white maps. The present volume is the third annual issue.

Properties of Inorganic Substances—a Second Revision and Enlargement of Tables of Properties of over Fifteen Hundred Common Inorganic Substances. By Wilhelm Segerblom. Pp. 226. (New York: The Chemical Catalog Co., Inc., 1927.) 6 dollars.

ORIGINALLY published in 1909 and revised in 1916, these handy tables for the working bench have now been considerably enlarged by the inclusion of new descriptive matter and by the treatment of some hundreds of additional substances. The arrangement is convenient, the abbreviations are self-explanatory, the letterpress clear, and the paper serviceable. Not the least useful part of the book is the index, which includes the common names of the compounds referred to in the tables. With the exception of some forty pages devoted to non-metals and rare metals, the scope of the compilation is confined to the metals and acids commonly employed in the study of qualitative analytical chemistry.

A. A. E.

Pheasant Jungles. By William Beebe. Pp. xiii + 248 + 47 plates. (New York and London : G. P. Putnam's Sons, 1927.) 3 dollars.

MR. BEEBE, who is Director of Tropical Research of the New York Zoological Society, travelled to Ceylon, India, Burma, the Malay States, and Borneo to search for rare pheasants and to study their habits. The results of his explorations have been published in technical papers. The present book deals with a few of his adventures, and is not a connected account of his travels. The reader receives an impression of a cheerful and intrepid explorer, who was undaunted by any dangers, difficulties, or hardships. His success was probably chiefly due to his sympathy with the wild tribes who live in the remote jungles that harbour the rarer pheasants. Without their help he could scarcely have reached his goal.

Mr. Beebe has generous praise for the few British who administer the remote jungle areas, and whose methods of handling the native races won his admiration.

### Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

## Barrier Reefs as a Sign of a Subsiding Coast Line.

In my letter on the recession of the Tahitian coral reefs published in Nature of April 23, proof is given of the original continuity of the present barrier reef from shore to ocean slope The absence of a lagoon from parts of the coasts of both Tahiti and Moorea should alone prove that barrier reefs can no longer be taken as an index of subsidence without independent proof from the adjacent land, and the completion of the proof that barriers may be formed from broad reefs of the finging type should be decisive. Further, I propose shortly to publish proof that in the adjacent but older island of Moorea there has been a tilting, resulting in subsidence of the south coast, which, though it took place during the growth of the reefs, has not made any difference to their form off that part of the island. The investigation of recf problems owes much to the numerous papers by Prof. Davis, which insist upon, and explain, the geological factors which it is essential to take into account. The biologist must, however, join in these researches, and it is much to be regretted that this side has been entirely neglected in Davis's work. One also misses any detailed local descriptions of the great series of reefs, old and new, which he has visited, that of Tahiti being the only one I have seen; this appears in French m Annales de Géographie, 1918 In this Prof. Davis gives reasons for believing that the island has undergone a large subsidence, with which conclusion, after much consideration given to the subject on the spot. I am quite unable to agree.

The evidences given are (1) the flats at the mouths of valleys, (2) certain bays on the south coast The former is inconclusive, the latter wrong in fact. The figure given of one of these valley flats, apparently the Reme Valley just west of Papeete, shows a practically sea-level flat penetrating far into the hills. In fact, the largest of these flats goes but a few hundred yards inland, and in no case is it level, all the streams having a rapid flow throughout their course also interesting to note that two of the largest flats are partially cut off from that outside the line of the old marine cliffs, by spurs projecting across the valley from one side. This is not shown in the figure given, but its presence very greatly reduces the extent of the flat which can be regarded as a drowned valley. evidence from these flats leaves the question open, unless corroboration can be found elsewhere. This is supposed to be found in (2) the bays of the south coast, which failing, we are justified in adopting the explanation of the formation of the flats which Davis mentions only to dismiss, namely, the wanderings of the streams from side to side of their valleys when they find their exits more or less blocked by beaches thrown

up by the waves, or by incipient coral reefs.

(2) There are no bays in Tahiti or the peninsula of Taiarapu I am surprised to see that Davis quotes 'Port Phaeton,' on the west side of the isthmus which joins the two volcanic cones, and certain much smaller which are connected with it. Now Port Phaeton is not a bay in the ordinary sense at all, being merely the space left between the two volcanoes which is closed at the east end by the isthmus, which is mainly formed by a long lava flow from the southern and smaller cone.

This space is further narrowed into a valley-like outline by the growth of reefs, and the alluvial flats which they support. It seems extraordinary that this origin of the bay should have been overlooked, since it is patent that there never was here a stream large enough to cut what would be the broadest valley in the islands.

The little bays which open out of Port Phaeton on either hand are very peculiar, but consideration of their formation requires more space than is at present possible. They are certainly not drowned valleys, nor ordinary stream valleys at all. Those not filled by alluvium or marsh are extremely shallow, while some of those on the south side of the 'Port' are merely patches of reef, covered with a foot or two of water, which were left when most of the surface was converted into land by banks, some of alluvium, others of coral debris

(3) Charts of the whole coast of these islands have been made with great detail and accuracy, and on a large scale, yet no scrutiny has revealed submarine evidence of submergence.

I also regret that Prot. Davis did not combine his geological observations with detailed examination of the reefs, and so discover how very partial, and even inaccurate, are the accounts given by his predecessors, whose views he discusses at length He personally examined the undersea banks within the reef, which is evidently what I term the submerged flat, but there are two important mistakes in his description. bank is not mainly composed of sand, which covers coral rock thinly and is often absent altogether, and, of the hundreds of the blocks of stone with which they are strewn and which I have examined, all are colonies of the coral Porites, more or less dead and often much decayed. They are not "arrachés au récif par les vagues de tempête." Though sometimes moved about, or thrown ashore where the barrier affords no protection, they all grew in this part of the lagoon, and they are never found on the outer slopes. There are no 'negro heads' on the actual edge of the reef anywhere, and I know of only four pieces of reef rock which have been tossed on to the surface from an overhanging edge. Porites colonies are common on shore reefs exposed to heavy surf, though judging from the slowness with which they blacken and decay, the addition of another to their number is a rare event.

The origin of the lagoon by the hollowing out of a once continuous reef is dealt with as follows the hypothesis of the formation of the lagoon by the progressive dissolution of a reef continuing to develop on its outer border is in contradiction with the luxuriant growth of corals inside the lagoon, where it forms little islands, and with the deposit observable in many places in the lagoon, of debris brought from the reef and volcanic materials of the island. growth, in most of the Tahitian lagoons, is greatly restricted. It is conspicuous near Papeete as the reef surfaces are covered in a remarkable way with corals, but there is practically none at all on the side of the reefs, and the long projecting shelves, which have been taken as evidence of rapid extension, are exactly the reverse. That the lagoons are slowly shoaling may be admitted pending proof; that they are becoming narrower is certainly untrue in many cases, doubtful in others.

Tahiti is not unique. Moorea differs in several ways but is a variation of the same type. Davis seems to have missed the cliffs of the northern part of this island, which are equally evident, and on the northwest are higher than the average of those of Tahiti. His criticism of Daly's theory of glacial control therefore fails in this case.

The four other islands visited are not described, and of their structure I can give no information. They are all older, and probably, as in Rarotonga, their cliffs have been disguised by subaerial denudation.

Much exploration remains to be done in this group, which I should consider myself fortunate to be able to attempt.

CYRIL CROSSLAND.

The Zoological Laboratory, Cambridge.

## The Variability of Long Diffraction Spacings in Paraffin Waxes.

So much interest is being manifested in the polymorphism of long chain compounds, particularly the fatty acids (Piper, Malkin, and Austin, J. Chem. Soc., 1926, 2310. de Boer, NATURE, 119, 50, 635; 1927. Thibaud, Compt. rend, 184, 24, 96, 1927. Muller, Proc. Roy. Soc., A, 114, 542; 1927), that it seems advisable to report the results of some X-ray experiments with ordinary commercial paraffin waxes. Only one mention of X-ray studies of these complex mixtures of many hydrocarbons has been made, that by Piper, Brown, and Dyment (J. Chem. Soc., 127, 2194; 1925), who found that the lines of the C28 hydrocarbon appeared alone for a paraffin wax although this fraction furnished only 16 per cent. of the mixture and other members as high as C32 were probably present.

In the present investigation samples were prepared from waxes melting at 135°, 130°, 125°, and 120° F. by solidifying on glass plates and photographing in an oscillating spectrograph with copper Ka rays. Solidification took place under identical conditions, since cooling from above the melting-points to just below occupied 30 minutes. Remarkably sharp lines for three orders only were obtained corresponding to single long spacings, besides the 'side spacing' lines. These were all measured with greatest care and checked against photometric curves. The results are

as follows:

Wax m p.	$d_1$	No. C Atoms indicated,		ide Spacings	d <sub>4</sub> .
135° F.	39·42 Å.U.	20	4·24 Å U.	3.73 Å.U.	2.56 Å.U.
130°	38 58	28 5	4·17	3.73	2.51
125°	35·22	26	4·44	3.88	2.44
120°	34 38	25	4·23	3.93	2.33

Particular care was taken in the measurement of the side spacings in order to discover any possible regularity in the slight variations running parallel with the change in the principal spacing. These were further studied with pinhole diagrams and molybdenum Ka radiation. There is apparently no such regularity.

Some experiments demonstrated that the rate of cooling of the liquid wax film was a determining factor in the spacings. The 135° wax was studied further in this respect with the following result:

Cooling		$d_1$ .	$d_2$ .	$d_2$ .	$d_4$ .
Instantaneous	:	36·64 Å.U.	4·12 Å.U.	3·82 Å.U.	2-58 Å.U.
2 mm .		37 84 *	4·16	3·82	2-60
10 mm		38 24	4·21	3·86	2-63
30 min .		39 42	4·24	3·73	2-56
60 min		40 20	4·13	3·82	2-60

It is evident that the longer the time given the molecules for orientation the greater the spacing for the same wax.

The presence of addition agents in small amounts

No. 3009, Vol. 1201

also affects the spacings, when the solidification conditions are kept constant, as shown by the following results on  $135^\circ$  wax with cooling during 10 minutes:

			$d_1$ .
Wax alone			38·24 Å.U.
., -11 pe	r cent a-naphthyle	ımine	38:315
	r cent diphenyl or		39.75
	per cent indigo .		40 70
	r cent. lead oleate		37.5

It is interesting to note that the translucency of the films measured with a Martin polarising photometer varied directly with the spacings, a property of practical importance in the manufacture of transparent waxed paper. The single exception is the wax containing soap. Lead cleate itself has a spacing of 37 5 Å U., and when added to paraffin wax even in so small amount as 1 per cent, seems to impress its own spacing upon the layers. It is still a matter of astonishment, not only that the principal spacing of a paraffin wax may be varied within limits almost at will, but also that these mixtures of as many as eighteen hydrocarbons with widely differing molecular longths form equidistant parallel diffracting layers at all. The explanation of the variability of the long spacing for the same wax is complicated by the fact that under different conditions different molecular lengths in the mixture predominate and also varying tilts of the molecules to the diffracting layers are possible. GEORGE L. CLARK.

Massachusetts Institute of Technology, Cambridge, Mass., U.S.A., May 12.

### Biological Fact and Theory.

Ir may seem scarcely sporting to intervene in a discussion between two such masters of controversy as Dr. C. Walker and Prot. J. S. Huxley, but there is a danger that ordinary biologists, in watching the clever play of these two duellists, may overlook the fact that the Mendelian theory so skilfully wielded by both is really a powerful weapon for the attack of biological problems.

Dr. Walker recognises that in many cases "the usual mode of distribution of the chromosomes between dividing cells before " (and after ?) " fortilisation, provides a perfect mechanism for the distribu-tion of 'genes'..." He then proceeds to criticise the 'Neo-Mendelian' theory on account of some apparent exceptions to this method of distribution, but this appears to be a hypercritical attitude. Exceptions are said to prove rules, and this "distribution of the chromosomes" is present in most cases of fertilisation. The exceptions are extremely interesting, of course; they should be and are being investigated, but what is the explanation of the normal behaviour of chromosomes before and after fertilisation? Dr. Walker would not claim that these very peculiar processes of reduction and fertilisation are present morely to mislead investigators, but he seems to think that they appear to be a perfect mechanism for the distribution of the genes and yet are not really such.

The transmission of paternal characters by the spermatozoon is not denied by Dr. Walker, and if he doubts the transmission of these characters in some way through the chromatin material of male sperm cell, there is very little left in the sperm. That would appear to make the problem more difficult still, and unnecessarily so. Admittedly it is difficult to imagine the potentialities (or half of them) for the development of an animal as being contained in the microscopic spermatozoon, but the facts of heredity indicate that they actually are. Then is it much more difficult to

believe that these potentialities are arranged in some sort of order in the individual chromosomes, since we know that both the potentialities and the chromosomes are there? The work of Morgan and others tends to show that certain facts in heredity are most easily explained by adopting such a theory, and there is no inherent impossibility in it in most cases, only there are apparent exceptions or difficulties in some instances which certainly require explanation, but these need not be regarded as fatal to the whole theory.

Dr Walker objects to the expression 'law' instead of 'theory,' and there, of course, most would agree with him. Taught by past painful experiences most scientists to-day would refer to any attempted explanations of natural phenomena as 'theories,' not laws,' but by all means let us make use of these theories so long as they are useful

J. S. Dunkerly

### Penetration of Radio Waves.

SINGULARLY little seems to be known as to the extent to which radio (wireless) waves will penetrate mto the ground, and yet information on this very point has become quite desirable masmuch as there are now two or three geophysical methods of ore prospecting which definitely attempt to use radio waves for the detection of ore beneath the earth

Experiments by one of the present writers, and others, in a mile-long tunnel at Montreal have indicated clearly that 40-metre waves could not be detected, at either end, when only a few hundred feet within the tunnel Broadcasting waves (400 m.) appeared to do better and were detected, with the help of good amplification, throughout the tunnel under an overload of 700 teet of limestone and igneous rocks Longer waves (10,000 m.) were detected yet more readily. But it remained uncertain whether these waves came into the tunnel through the air, or along the rails and electric wires, or whether they came through the rock. The only sure thing is that the 40-metre waves did not ponetrate to the centre of the tunnel by any of these means. Experiments by the U.S. Bureau of Mines at a mine near Pittsburgh indicate similar results, for although initial experiments seemed to point to the passage of radio waves through rocks, yet further experience showed that rails or wires were acting as carriers.

Experiments with submerged submarines prove that radio waves will not pass more than about 50 or 60 feet into seawater, no matter what the wave-length. But the question of penetration into fresh water, damp rock, and dry rock remains uncertain. Moreover, in ore prospecting, distances are used immensely less than the wave-lengths employed, and it has been asked whether we have to contrast radiation and induction, a convenient distinction well brought out in Dellinger's paper ("Principles of Radio Transmission," Sei. Papers, Bureau of Standards, vol. 15, p. 441), although of course at a given point and instant there can be but one electric vector and one magnetic vector.

The real object of this letter is to express the hope that some wireless enthusiasts may have the opportunity of making experiments underground in cave, tunnel, or mme which is absolutely devoid of wires or other conductors, and where the windings from the entrance are sufficiently devious to preclude the passage of waves through air down to the receiving apparatus consisting of coil, amplifier, and receiver Accurate measures of signal intensity would only A. S. Ěve. be still more valuable.

D. A. KEYS.

Bureau of Mines, Washington, June 7.

### Metosis in a Triploid Tulip.

Bridges and Anderson (Genetics, 10, 418-441, 1925) have shown by genetic experiment that in Drosophila trisomic in respect of the X chromosome, the chromosomes concerned are in the two-strand stage at the time crossing over takes place, that any strand may cross over with any other strand and that "two strands which have crossed over with each other are as free to cross over with a strand from the third chromosome as with a strand from the original two chromosomes "

Synapsis in triploid Diosophila has not been figured. but the description of crossing over given above applies exactly to the mode of pairing of the chromatids in Fig. 1, which is a diagrammatic drawing of a pachytene trivalent chromosome in a triploid tulip. Fig. 2 is a commoner form of trivalent in the same variety, and indicates the probability of a diminution in crossing over towards the middle of the chromosome as compared with the diploid if crossing over is indeed

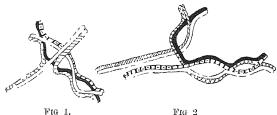

Fig 2

associated with pairing. A diminution from one end towards the middle region has been shown (Bridges

and Anderson, loc. cit).

It is not possible to suppose that this chiasmatypy or exchange of partners among the chromatids, whether in triploids or diploids, is a direct cause or consequence of genetic crossing over. The agreement between what is observed in the cells and what is required by the crossing-over hypothesis would, however, be explained if (1) pairing is a condition of crossing over, (2) pairing takes place between chromatids, not between whole chromosomes, and (3) chromatids remain together in pachytene and diakinesis for that portion of their length where they have been paired.

A full description of meiosis in various triploid tulips and hyacinths, together with a discussion of the

points raised, will be published later.

John Innes Horticultural Institution, Merton, S.W.19.

#### The Hythe Skulls.

I FEAR Prof. Parsons (NATURE, June 18, p. 893) has not recently consulted his own paper.

Miss Hooke writes (Biometrika, vol. 18, p. 22). "The Hythe crama are in all probability those of Kentish men, dating back to the fourteenth and fifteenth centuries.

Prof. Parsons wrote in 1908 when publishing his memoir (Journal of the R. Anthropological Institute, vol. 38, p. 422): "It is probable that we are dealing with the remains of Kentish people most of whom lived in the fourteenth and fifteenth centuries."

Miss Hooke writes (loc cit): "Measurements were made on 590 cranıa selected from at least double that number "

Prof. Parsons wrote (loc. cit). "It may not be out of place to say here that the 590 skulls which have been measured consist of those which were picked out of the stack in 1851 and placed upon shelves, where they are now shown.'

The Oxford Dictionary's first equivalent for 'pick out' is 'select.' Miss Hooke neither directly nor indirectly suggests whether the selection was a 'random selection' or a 'biased selection.' not know what her views on that point may be. Personally, I think a series of crania extracted from a much larger heap for show on shelves is liable to "It was evident be biased. Prof. Parsons wrote from the debris that women's and children's skulls had, owing to their tragile nature, suffered more seriously than those of men, and this fact no doubt accounts largely for the excess of male over female skulls on the shelves" What Prof. Parsons wrote in 1908 would apply equally well to the more slender and lightly built crania of mon as well as of women. It is a sound rule of craniometry that all fragments should be pieced together where possible, and all broken crama should have their available measurements taken, otherwise the selection is far from a nandom sample, but consists of the thicker and very often the larger crania. The Hythe crania are worthy of careful study, but that study involves four or five years of continuous work, with the piecing together of fragments and a complete system of measurements on every available skull

THE EDITOR OF BIOMETRIKA.

### Surface Structures of Fractured Flints.

RECENT letters in NATURE by Reid Moir and W J. Lewis Abbott on surface structures of fractured flints prompt this note.

We had hoped to learn, by a study of the patina, the elapsed time since the original chipping was done. In some cases the patina seemed to be due to dehydration, but in any case it is caused by 'weathering,' and the depth of the patina depends on climate and time. The velocity coefficient of such reactions should be determinable, and an extrapolation for local conditions might give at least interesting results.

We found the first to be of so many varieties, when judged by surface changes due to heating, that no orderly report is possible. But a peculiarity in the case of English flints from Grime's Graves may be of interest. The surfaces of these old flints received from Mr. Reid Moir are nearly white (weathered). The interior is transparent to translucent and is scalbrown in colour. After heating at 600° C, for several days, a fresh-cut surface of this flint apparently remains unaltered, or takes on a clear, varnished appearance. A surface having the patina of ago retains it on heating, but discloses the transparent, varnish-like layer beneath.

The mass of the flint, except for these surface effects, is completely changed to a white, opaque material. In other words, high temperature in the case of this particular flint exactly reverses the apparent effect one might expect from weathering. The white patina of Nature is replaced by a transparent surface, and the inner mass appears 'weathered' or white. Can this be due to the rupturing forces of contained water? It does not occur in American so-called flints.

## Smooth Electrodes for pH and Conductivity Measurements.

A COMPARATIVE study of different electrodes for the determination of the concentration of hydrogen ions has shown us that quite excellent results may be obtained with platinum electrodes covered electrolytically with gold and with a quite thm smooth metallic layer of platinum, iridium, rhodium, or palladium. A constant potential may be reached in a much shorter time than with the same metals in the form of a black deposit.

This led us to try the same electrodes for conductivity measurements. Electrodes coated with gold and metallic platinum proved to be much superior to electrodes coated with platinum black. Under conditions where with platinum black. Under conditions where with platinum black electrodes it was difficult to find the minimum of sound, with platinum-gold-metallic platinum electrodes the minimum (even m methyl-alcohol solutions) was extremely sharp. On the other hand, electrodes coated with gold and rhodium gave us unsatisfactory results. We are not quite sure yet about indium and palladium electrodes.

In this connexion it is interesting to note that a platinum foil coated with gold and metallic platinum acts catalytically on a mixture of hydrogen and oxygen, whereas iridium, rhodium, and palladium under the same conditions do not act catalytically or very feebly. We hope that a further study of these thin layers of metals of the platinum group will permit us to establish more clearly their catalytic properties.

University, Leningrad, June 11.

#### Florentium or Illinium?

My attention has been directed to the statement of Prof. Rolla in Nature for April 30, p. 637, in which he claims priority for the name florentium for element No 61. He says: "We believe, then, that the priority in the discovery of element No. 61 belongs instead to those who first had sure data as to its existence."

On this basis the name illinium deserves priority. The fact that Prof. Rolla deposited a plico suggellate instead of publishing his paper, demonstrates that he was not, at that time, sure of his discovery. When Harris, Hopkins, and Yntema published their paper and gave to element No. 61 the name illinium, they were sure of their results on the basis of four independent lines of evidence: (1) The 135 spectral lines referred to m NATURE (Feb. 26). (2) The concentration of illinium in rare earth fractions between needlymium and samarium. (3) An absorption spectral band characteristic of illinium. (4) The N-ray spectra.

### Specimens of Tropical Timbers.

It may perhaps interest some readers of NATURE who are concerned with the study of tropical timbers, to know that a certain number of duplicate timber speamens from the Burma type collection are available for distribution to museums or research institutions.

The specimen blocks, which are 6 m. 4 m. 2 in. in size, have been made from trees which have been individually identified botanically, with check identifications at the Forest Research Institute, Dehra Dun, and at Kew, the original sheets being in the forest herbaria at Maymyo and Dehra Dun or in certain cases at Kew.

No charge will be made for the specimens except for packing and freight.

A list of the species available can be obtained from the undersigned.

No. 3009, Vol. 1201

## Irrigation and Crops.1

THE deleterious effect of irrigation on the soil, and therefore on the crops grown when it is not duly balanced by drainage, are described simply and clearly in an important memorandum drawn up by Dr. B A. Keen, of Rothamsted, for the Empire Marketing Board The memorandum is the work of an experienced soil physicist, and deals in summary form with the chemical and physical reasons for the accumulation of soluble salts on the surface of the ground, usually but somewhat erroneously described as 'alkalı.' Such concentration can, obviously, only take place where there is great evaporation of soil moisture, but little or no rain to wash the salts away, and the parts of the world where these conditions prevail are somewhat clearly defined. Taking the rainfall map as our guide, it can be seen at a glance that the amount of rain falling in the temperate and tropical regions is generally what may be called ample for crop production. But, round about and just outside the tropics of Cancer and Capricorn, belts of little rain or deserts are met with in the Old World, while in the New such tracts are confined more or less to the western sides of the continents These conditions are due, in the main, to the distribution of the ocean winds and currents. Clear skies are met with in these tracts, which in the local summer are connoted with intense heat and great evaporation of the soil moisture; whereas within the tropics the amount of cloud is much greater, the retarding force of the sun on vegetation is less, and a greater amount of rain falls.

Dr Keen points out that it has been estimated that one-third of the earth's surface receives 10 inches or less of rainfall in the year, while another third has under 20 inches; also, that at least 100 million acres of the world's crops, or 7 per cent., are under irrigation. This latter figure appears to us to be an extremely conservative figure, that is, if 'irrigation' has the usual meaning. For rice alone would probably account for a good deal more than the area named. In India the great bulk of this crop is irrigated, and there are 80 million acres of rice grown, while there are vast tracts in China and the East generally to be added.

It is, however, evident that it is the first-mentioned third that Dr. Keen has in mind while discussing alkali. He enumerates the factors concerned in the development of successful irrigation projects, and divides these into three main classes. economic, engineering, and scientific. The latter he rightly regards as fundamental, although the others may, in practice, easily become limiting; and classes them, roughly, as the composition of the water used for irrigation, and the chemical and physical properties of the soil, these factors being significant, both in schemes newly laid down and in old-established systems.

The chief part of the memorandum is devoted

<sup>1</sup> Irrigation in the Empire. Memorandum and Questionnaire. I Dr. B. A. Keen. (London: Empire Marketing Board, May 1927.) to the discussion of the importance of these scientific factors. Dr. Keen summarises and arranges, in an illuminating manner, the results obtained by the scientific workers on the spot, chiefly Russian and American, as to the causes of alkali and the scientific methods of fighting it The effect on alkalı land, when irrigation is commenced, is then elaborated in some detail. One important result is the chemical change induced in the constitution of the clay particles, that is, those which, though minute, are capable of aggregation into groups by what is called flocculation-which, indeed, is or should be the object of all cultural operations. Here the 'calcium clay' is in danger of being converted into 'sodium clay,' because of the large proportion of this latter element in the soluble surface salts now let loose This change renders flocculation in the soil difficult, and the soil becomes sticky and unworkable: and, if it is not checked in time, the presence of carbonic dioxide in the soil air induces a further and more dangerous change, namely, the formation of carbonate of soda, which is both toxic to vegetation and destructive of the physical character of the soil.

The tolerance of plants to alkali is briefly described. The crops mentioned are chiefly those of sub-tropical and warm temperate regions; and Dr. Keen quotes Russell, as giving maize the place of high sensitiveness to alkali, with barley and lucerne less so, while the date palm is mentioned as the least sensitive of all crops grown. The corresponding plants in warmer regions are given as sorghum, cotton, rice, and berseem: this correspondence cannot, of course, apply to the order of sensitiveness, which would probably be rice, cotton, berseem, and sorghum, the latter being among the most resistant cereals to alkali.

In a discussion of the dangers of deterioration in irrigated areas, attention is directed to the harmful effect of the change, from basin irrigation in the Nile Valley, with its beneficent summer fallow, or 'sheraqui,' to perennial irrigation, rendered possible by the larger supplies of summer water made available by the erection of the Assouan dam. It is pointed out that the gradual rise in the water table, lowering as it does the. root range of the crops, shows once for all the importance of adequate drainage being provided in all new irrigation schemes Attention is also directed to the tendency towards the application of excessive quantities of water to the crops, when this is left in the hands of the farmers, the example given being the interesting experiments conducted by the Howards on the growth of wheat in the Quetta valley.

Dr Keen concludes his paper with brief references to the importance of the study of the duty of water for each crop grown under irrigation, with especial reference to the quantity needed at each stage of growth the maintenance of tilth in irrigated land and its hindrances; and certain cases where alkali is not responsible for cultivation

difficulties. We presume that the troubles attendant on an undue proportion in alluvial lands of silt particles, that is, those too small to be flocculated, would come under this head. This is one of the main difficulties in many alluvial lands in the

tropics

Dr. Keen thus includes only a part, although an important part, because of the costly irrigation projects entered into, of the irrigated areas within the British Empire. This is probably because the Marketing Board has in view other discussions on the But the author has probably remaining portions purposely limited himself to the rain division mentioned above, and confined himself in India to the rainless Indus plain, thus leaving out the greater part of the Gangetic plain, where alkalı conditions have probably been the bugbear of agriculturists almost since prehistoric times. Leaving, then, these narrow limits, some further remarks may be made on alkali conditions found within the tropics, and then on some further lessons which may be learnt from irrigation generally in other lands in the tropics.

Alkali is of much less importance within the tropics, partly for the reasons already mentioned, but also because of slope, and the washing-out effect of the greater volume of rain falling every year. But it is just as liable to present itself, wherever the rainfall is scanty and the evaporation great, as it is in the typical desert regions dealt with by the author. The writer of this article had the interesting experience, during the last seven years of his work in India, of fighting this evil . and growing sugar cane, one of the least resistant of crops, on saline land the irrigation of which was from a series of more or less brackish wells. It would be a mistake to assume that the people of India, with their highly developed systems of agriculture, have made no effort to counter the action of this insidious enemy to crop production. The remedies employed are practically endless, varying from simply scraping away the efflorescence (by which with little labour one-third of the salt concentration may be removed at a time), through palliatives such as carting silt on to the ground in their annual cleaning out of the irrigation tanks, introducing a rotation with some salt-resistant crop, such as irrigated ragi (Eleusine coracana) or even growing babul (Acacia arabica) for a term of years, and thereby making a profit out of it, or digging in a green manuring crop, to flooding the land when it is possible to do so. Many of these remedies were tested by the writer, with varying results; and ultimately success was obtained by enlarging and using the well which had the sweetest water and using it in sufficient quantity to mitigate the evil effects of its brackishness, green soiling, and introducing a suitable rotation after it, with sorghum immediately before plant ing the sugar cane

Irrigation extends throughout the length and breadth of India, and is not owing to any deficiency in the total annual rainfall, but rather to its unequal distribution over the year. This is characteristic of the Old World continental masses, as contrasted with the New, where the

ram is more or less equally distributed (and many British African colonies) is in the region of periodic rains, there is usually a short period each year when heavy rains fall, this being followed by a longer period of little or no ram. The growth of crops during the ramy season is insufficient to provide food for the great mass of population, and the excess water has thus to be conserved as much as possible for growing additional crops during the rainless period also. This, of course, is more especially the case with crops requiring much water, such as rice, which is grown in six mehes of flowing water throughout its growing period, and sugar cane which, in the peninsula at any rate, needs water at frequent intervals throughout the year. The large area under rice has already been referred to, and there are some three million acres of sugar cane grown Alkali is rarely a matter of serious moment in the peninsula, either as regards rice or sugar cane, or the various other crops irrigated; and much the same applies to the great irrigated areas farther east

The duty of water is known in a rough-andready way for most of the crops grown, that is, the small quantity needed at first, the great increases when the roots have developed and the leaves reach their maximum expanse, and the shutting off of water when ripening approaches. But there is a fine field open for scientific study in this matter; for example, along the lines adopted by the Howards, as to whether equally good crops of rice may not be obtained by using less water, and thus extending the area, which is badly needed: most of India is very like a desert when the dry spell has had sway for some time. Much of this irrigation is on undulating land, and full advantage is taken of this: the Indian cultivator, without the aid of instruments, has an uncanny knowledge of the problem of leading the water from field to field in the right direction. There are few of the great flat areas of the reclaimed deserts referred to by the author, and the gradients of rice are surprisingly steep in places.

Attention may be directed, in conclusion, to the work done in recent years in the Hawaiian Islands, where the crop is almost entirely sugar cane, and where the theory and practice of irrigation has been very fully worked out as regards this crop In three of the four islands of the group where the sugar cane is grown, the great proportion of it is irrigated. There is a plentiful supply of rain brought by the trade winds and falling on the east sides of the islands, but the amount drops practically to desert conditions on the west. This is countered by collecting the surplus rain on the eastern side and carrying it by tunnels through the mountains and by aqueducts across the valleys from one side to the other, until actually more cane is grown on the western side than the Seepage is countered by lining the eastern. channels with reinforced concrete made in slabs It was found that the grit in the on the spot water seriously abraded the sides of the canals, so a system of settling tanks has been instituted

with very satisfactory results. But the most remarkable fact is that irrigation has been found to pay, even where the rainfall is heavy enough to grow luxuriant crops of cane. This can only mean that the duty of water has been very carefully worked out

Such, indeed, is the case Every estate is mapped out with contour lines, and a whole series of canals, ditches, and so on, is drawn on these plans; and the amount of water given to each field or section is frequently measured, and recorded throughout the growth of the canes Numerous curves are prepared, on which a great deal of information is presented. One of the most remarkable of these is the curve of profitable

irrigation which can be applied for each month of the twenty-four during which the cane is in the ground. Few countries can follow Hawan in the vast expense involved in its irrigation system, but many useful suggestions would doubtless be obtained from a careful study of the work done in this group of islands by all interested in the duty of water. The difficulty, mentioned by Dr Keen, as experienced in cultivation because of the irrigation channels, lastly, is got over in various ways . by the obvious one, of using elongated plots as units, by movable pipes for the last distribution of water; and even by the use of overhead water sprinklers, also removable, in place of irrigation furrows C. A. B

### The Future of the Smithsonian Institution, Washington.

MEN of science in Great Britain had regretfully known for some time, through correspondence with friends in the United States, and by sundry opportunities of personal intercourse and discussion, that all was not well with the Smithsonian Institution in respect of its future scope and activities—that, notwithstanding the achievements of the past eighty years (it received its charter in 1846), perplexing uncertainties had now arisen regarding the specific objects which the organisation should direct and control. The Smithsonian is, in fact, at the cross-roads of endeavour, largely due to the very magnitude and completeness of its early conceptions.

Aware, in fullest measure, of their onerous responsibilities, the Chancellor of the Institution. Chief Justice Taft, and his colleagues on the Board of Regents, decided to summon a conference of representative American citizens, professional and lay, "To advise with reference to the future policy and field of service of the Smithsonian Institution." This conference took place at Washington on Feb. 11 last. Only three days earlier the death had occurred of Dr. C D. Walcott, who had been Secretary of the Institution since 1907. From the report of the proceedings, which is now available, it is evident that the problem set, in chief, the provision of adequate funds for maintenance and continued development, received sympathetic recognition Among those present were such well-known men as Dr. W. W. Campbell, President of the University of California; Mr. Robert W. Bingham (Kentucky); Mr Charles F. Brush (Ohio), Dr Simon Flexner, Director of the Rockefeller Institute for Medical Research; Mr. Robert P Lamont (Illinois); Dr Merriam, president of the Carnegie Institution; Mr Ogden L. Mills (New York), Dr H. F. Osborn, Dr. S. W. Stratton, president of the Massachusetts Institute of Technology; Dr. George E. Vincent, president of the Rockefeller Foundation; Dr W. H. Welch, of Johns Hopkins University, and Mr Robert Winsor (Massachusetts).

The Smithsonian Institution is everywhere such an accepted factor in the world of science that few, perhaps, are immediately prepared to recall its

initial testamentary story, or the genesis of the foundation which perpetuates the name Smithson.

James Smithson was an Englishman. In his earlier years he was known as James Lewis Macie, his mother being the widow of James Macie, a country gentleman, who had resided near Bath. Born in 1765, young Macie was in due course entered at Pembroke College, Oxford, as a gentleman commoner, graduating there in 1786. Chancellor Taft, in his opening address to the recent Conference, recalls, neglecting needless reticence, that Macie was the natural son of that Hugh Smithson who, from the baronetey of the realm. became the first Duke of Northumberland. At Oxford, Macic showed a marked predilection for scientific studies, and, as Dr R. T. Gunther has recently pointed out (NATURE, April 2, p. 492), opportunities for such pursuits actually existed at Oxford at the period of his entry. Finally, in digression, the bar sinister on Macie's escutcheon was met, after his father's death—the precise date is unknown—by a successful application to the Crown to assume the name of Smithson.

Our Royal Society elected Macie a fellow on April 19, 1787, when twenty-two years old, and on the subjoined certificate: "James Lewis Macie, Esq., M.A., late of Pembroke College, Oxford, and now of John Street, Golden Square, a gentleman well versed in various branches of Natural Philosophy, and particularly in Chymistry and Mineralogy, being desirous of becoming a Fellow of the Royal Society, we whose names are hereunto subscribed do, from our personal knowledge of his merit, judge him highly worthy of that honour and likely to become a very useful and valuable member—Richard Kirwan, C. F. Greville, C. Blagden, H Cavendish, David Pitcairn."

The first scientific paper of the newly elected fellow was read on July 7, 1791, before the Royal Society, and in the name of Macie It was published in the *Philosophical Transactions*. According to the late Dr. S. P. Langley, the name of Smithson is first certainly known to have been used by him in connexion with his second communication to the Royal Society, read on Nov. 18, 1802.

Smithson died on June 27, 1829, at Genoa. Three years earlier he had made a will whereby he bequeathed (in case of the death of a nephew without heirs) his entire estate "to the United States of America, to found, at Washington, under the name of the Smithsonian Institution, an establishment for the increase and diffusion of

knowledge among mcn."

The proposed gift was first publicly announced by President Jackson in a message to Congress in 1835. The amount of the fund devolving was £111,389. We see that the donor had relegated his alma mater, and had passed over an ancient scientific foundation. Born in France, brought to England and naturalised, and in later years living among foreigners, Smithson may have become so detached in thought and habit that old ties, old associations, were forgotten. Conjecture surrenders to fact. But the use made of the gift as the keystone of an arch of knowledge was altogether unprecedented in character and optimism.

Ten years of travail and debate preceded the launching of the Smithsonian. The problem was to define knowledge and determine how best to increase and diffuse it. What was to be inscribed on the arms of the direction post? Five successive Congresses discussed the question. Many diverse propositions were made. Towards the end of

1846 a charter passed into law.

The first secretary was Joseph Henry, professor of physics and of natural history at Princeton. To his vision, zeal, and resource was due the organisation and the planning of projects for the Smithsonian Institution. Henry was succeeded by Prof. Spencer F. Baird (1878), biologist, he in turn by Dr Samuel Pierpont Langley (1887), physicist and astronomer; next by Dr. Charles D. Walcott (1907), geologist and

palæontologist.

Activities of great public value arose through Henry's influence; for example, the Weather Service, the U.S. Fish Commission, the system of International Exchanges of Scientific Literature, and the Bureau of Ethnology. There followed, under later leadership, the National Zoological Park, an Astrophysical Observatory, and other notable enterprises, each fostering research and progress. For long they were financed from the income of the private Smithsonian endowment. Congress now apportions certain sums for their maintenance, because, Dr C. G. Abbot remarks, "the public needs them." Most of them are, however, still under Smithsonian administration. With reference to Congressional appropriation, we gather from Senator Reed Smoot, who spoke at the Conference, the unwelcome information that "the handicap under which the Smithsonian Institution labours in its relations with Congress is that Congressmen know so little about it." The Institution co-operates through specimens, instruments, men, and advice, with scientific agencies throughout the world. It has promoted the scientific survey of North America, and has taken part in no fewer than 1500 expeditions in

various regions. Researches by men not directly connected with the Institution are subsidised at intervals, these not Americans alone, but Englishmen, Frenchmen, Germans, and other nationals. The Smithsonian publishes new knowledge gained by its own and outside workers in the form of large memoirs and smaller original papers, which, with unique liberality, it distributes to 1500 libraries and learned bodies in every country of the world Its reprints in the familiar Annual Report of informing articles of distinction are well known This was a matter in which Dr. S. P. Langley took personal pride and interest. Here it may be recalled that during Secretary Henry's term of office, he addressed a letter to the British Association pointing out the advantage of publishing systematic lists of the titles of scientific papers As a sequel the Royal Society began its well-known "Catalogue of Scientific Papers."

Some quotations from recorded speeches at the Conference will serve to convey the general views of at least a few of the representatives present. Characteristic throughout was the enthusiastic affection entertained for the Smithsonian. Dr. C. G Abbot gave an able summary of accomplishment. "Considering," he said, "the immense benefit which the foundation has brought to our country, it would be ungrateful to transform the private memorial character of the Institution into a Government agency. The Smithsonian is not just another institution; it is not just another museum, not just another university." Dr Flexner is of opinion that "the Smithsonian makes an appeal on the one hand strongly to Government and equally to private philanthropy; because the fruits of science, however garnered, are something of which the public as a whole, without distinction, enjoys the benefit." Again, Dr. W. W. Campbell: "Men of the type of university professors or investigators are in need of favourable environment; they are in need of tranquillity; they must be men without worries; there should be a continuing financial policy." Dr. Osborn, as regards scientific research: "I remember well when Secretary Langley was laughed at for diverting the funds of the Institution to experiments in flight. would suggest that they were not valuable to-day, when the world is covered with airplanes?" Also Dr. George E. Vincent: "I am sure that out of this Conference there will develop a plan by means of which private citizens and the Government of the United States will combine to make this great Institution still more influential in the future."

In Great Britain many friends will watch with deep interest the effort that is being made to re-awaken and intensify appreciation of the Smithsonian Institution. The Conference delegates stand high in public esteem in the United States; they are of the type capable of moving men to action where action is imperative. may be hoped that a satisfactory response will ensue respecting the 'field of service' under discussion. T. E. JAMES.

### University College, London, 1827-1927.

THE centenary celebrations of University College, London, which were maugurated by Their Majesties the King and Queen on Thursday, June 23, continued day by day until the end of the ensuing week. To-day, July 2, they are to come to a joyous conclusion with a dance in the Great Hall, a building recently acquired and reconstructed by the College and dedicated as a war and centenary memorial on June 24 by H.R H Prince Arthur of Connaught. The celebrations have been on a scale befitting their august patronage, and the programme of receptions, divine services, concerts, lectures, and demonstrations arranged for the delectation of the visitors, shows that the College was determined to rise to the height of this opportunity Specially noteworthy have been the lectures, more than forty in number, including many by such well-known authorities as Sir Flinders Petrie, Profs. J. Norman Collie, M. J. M. Hill, A. V. Hill, and Daniel Jones, and Sir Frederic Kenyon. These, and numerous demonstrations and exhibitions of great interest, were freely open to the public

The circumstances in which University College came into being are vividly recalled in the brilliant oration pronounced by the Provost, Sir Gregory Foster, on Mar 25, 1926, before the Union Society of the College at a gathering organised by it to commemorate the names of founders and other illustrious members The founders' names selected for mention on that occasion were Dr. George Birkbeek and Isaac Lyon Goldsmid The former, who also founded, in 1823, the Birkbeck Institute, now enrolled as Birkbeck College among the Schools of the University, was engaged about that time in association with Henry Brougham, afterwards Lord Brougham, in a campaign for promoting the education of the people, a campaign which led to the foundation of the famous Mechanics' Institutions. Goldsmid was a leader in the efforts that were being made in favour of religious toleration. Both movements were important factors in producing an atmosphere favourable to the reception of a scheme for a

metropolitan university.

Many other distinguished men had, for several years before the laying of the foundation-stone of University College in April 1827, been canvassing the merits of such a scheme. Among them were the poet Thomas Campbell, George Grote, Joseph Hume, the Marquess of Lansdowne, Zachary Macaulay, James Mill, the Duke of Norfolk, and William Tooke Francis Place, the "radical tailor of Charing Cross," also interested himself in the matter. It was Thomas Campbell who first put the project on paper Fired with enthusiasm for the idea incorporated in the constitution of the then newly founded University of Berlin of devotion exclusively to the interests of science and learning without bias towards any particular creed or school of thought, he wrote a letter to Lord Brougham, which was published in the Times of Feb. 9, 1825, advocating a "proposal for a

metropolitan university for effectively and multifariously teaching, examining, exercising, and rewarding with honours in the liberal arts and sciences" youths of from fifteen or sixteen to twenty or more years of age whom their parents could not afford to send to Oxford or Cambridge. This letter, despite disparaging editorial comments, led directly to the foundation of the University College. The movement was borne forward on a wave of generous enthusiasm for the advancement of learning and revolt against the dominance of academic particularism, privilege, protection, and repression.

To the wisdom and foresight of the founders Lord Balfour paid a remarkable tribute in his speech at the dedication ceremony in the Great Hall on June 24 last. Their work stands out, he said, as being little short, if short at all, of the boldest genius. "How many were there — who saw the great part science was going to play in civilisation? Very few But they foresaw it, and while foreseeing it . . . they did not ignore or minimise the humanities"

It is precisely this judicious appreciation of the place of science in university education, coupled with a fine record of achievements in the fields of scientific research, that constitutes the most cogent argument for our gratitude and further support. We are reminded that its chemical laboratory, opened in the College in 1828, was one of the earliest places in England where chemistry was systematically taught. In that department Sir William Ramsay, following a line of distinguished predecessors—Edward Turner, Thomas Graham, A. W. Williamson—did fundamental work on the gases argon, neon, and helium, and from it went forth many a young chemist trained by him and eager to follow in his footsteps. Biology, like chemistry, was almost unknown as a subject of university study until University College began teaching it, and systematic medical education based upon scientific principles, carried out in a hospital built for medical purposes, was equally a novelty Prof. Sharpey introduced the teaching of histology as a branch of physiology, and two of his pupils, Sir, Michael Foster and Sir John Burden Sanderson, carried his methods to Cambridge and Oxford. The department for "Engineering and the Application of Mechanical Means to the Arts, which figures in the first programme of studies, did not immediately materialise, but later on a chair of engineering was instituted which was held successively by Profs. Vignoles, Hodgkinson, Fleeming Jenkin, and Alexander Kennedy Here, too, the College blazed a trail that has been followed by the other universities.

In short, the College is justified in claiming that it has played no small part in that progress of science to which is largely due the great transformation in the religious, the political, the social, and educational aspects of our national life which has taken place in the past hundred years. Nor should we forget that the College was a pioneer in

giving the advantages of higher education to women, in establishing a complete university school of fine art, and in introducing the teaching of librarianship and phonetics

As the circles of its influence have widened and the fame of its teaching has spread, the College has attracted more and more students, including many from far distant lands. In the past twenty-five years this growth has been rapid—from 1098 to 3228. Though the fees have been raised the increase in the fee income is but a fraction of the increase of expenditure entailed, and the College must look for fresh sources of revenue. The Centenary Appeal asks for £520,000, including £235,000 for endowment of chairs, of which seventeen are at present without endowment, and seventeen others are inadequately endowed. Up to June 18 the appeal had brought subscriptions

amounting to £117,440, including £43,000 contributed by past and present students, and a grant of £25,000 by the Rockefeller Foundation for endowment of the Department of Pharmacology, while on June 23, the first day of the celebrations, appeared an announcement in the *Times* of a turther gift of £93,178 from the same Foundation, supplementary to the gift of 1921, for the Departments of Anatomy and Physiology

Of good omen for the future of the College is the purchase by the University of London of eleven and a half acres of land in its immediate vicinity. This momentous transaction, made possible by a gift of £400,000 from the Rockefeller Foundation and a Government grant of £125,000, synchronises auspiciously with the centenary celebrations, and suggests vistas of further progress for the College not less glorious than that already achieved.

### News and Views.

There would appear to be good ground for believing that another sensational archaeological discovery has suffered the fate of many of its kind in the past and has failed to stand the test of examination by experts. The remarkable character of the finds at Glozel, in which objects of neolithic culture akin to the Ægean, inscriptions on clay tablets, and engravings of animals on pebbles were found in association, aroused no little scepticism at the time of their discovery; but Dr. Salomon Reinach was convinced of their authenticity and, relying upon their evidence, put forward the theory that a degenerate Magdaleman culture had lasted so late as 4000 3500 B.c., with the consequence that the Magdaleman must be placed so low as 5000 B.c. The resemblance of the script on the tablets to that alleged to have been found in a Portuguese dolmen in 1894 was immediately apparent. It has been stated that a confession of forgery has appeared in Belgium, but confirmation of this is not yet to hand. In the issue of Antuquity for June, Mr. Crawford gives in some detail the results of an examination of the objects themselves, and subjects the circumstances of the find to a critical scrutiny based upon a personal inspection of the ground. He is persuaded that the objects in question are forgeries. His case is convincing; all the more so in that his opinion coincides with that of the Abbé Breuil.

In connexion with the centenary celebrations of University College, London, it will be remembered that George Grote, the distinguished historian and publicist, was in especial measure the early friend and counsellor of the College. He was holding office as president at the date of his death in 1871. It is worthy of recall that on July 7, 1863, eight years before Grote died, he communicated the following wishes: "I desire that after my decease my cranium shall be opened by the Professor of Anatomy in University College, London, or by some other competent anatomist. I desire that my brain shall be carefully weighed and examined, and that

the weight thereof shall be communicated to Prof. Bain, together with any other peculiarities which may be found, especially whether the cerebellum is deficient as compared with the cerebrum." After the historian's decease, Prof. Sharpey, finding that Bain desired to be relieved from participation in the foregoing directions, entrusted the autopsy to Prof. John Marshall, who published a description of the brain (with photographic illustrations) in the Journal of Anatomy and Physiology (vol. 27, 1893). It would be of interest to learn in whose keeping the brain remains. It is not at University College,

The Electricity (Supply) Act, 1926, has raised the hopes of consumers for getting a cheaper supply of electricity in the immediate future. The Act gives facilities for shutting down all uneconomical generating stations and erecting and enlarging modern works equipped with the best generating plant available. The immediate problems in connexion with transmission and distribution are the obtaining of way leaves and the most economic methods of creeting overhead lines. Once it is conceded that no landowner should have an absolute veto to prevent transmission lines passing over his property, it is highly desirable that the present method of obtaining way leaves should be simplified. It is true that the Post Office is in a specially favoured position and has almost absolute powers to prevent its telegraphs and telephones being interfered with either by leakage or induction from power-lines, but it has never used its powers unreasonably. Hitherto, electrical development in Great Britain has been based on coal conservation, but the heavy costs of the transmission lines makes it probable that 'capital' conservation is equally important. We think that by far the most promising method of reducing costs is to utilise to the utmost all the plant in the station. To have the great bulk of the machinery lying idle for most of the day is most uneconomical. Some method of storage must be used and each machine run to its full capacity. Periods of light load are a loss to every

undertaking. The most promising method of fully utilising the plant in winter time is to have some low grade thermal storage system in consumer's houses for hot water and room heating. Several systems for this purpose are being tried, and electrical engineers would do well to encourage them. Once they become general, considerable reductions in the price of electricity will be possible.

IT is highly desirable that nothing be done to detract from the beauty either of a town or of a countryside. Yet just as it is necessary for an individual to consider ways and means, so it is necessary for us to encourage industry even at the expense of detracting from the beauty of the land in which we live. Railways, telegraph poles, coalpits with their mountains of shale, and brick-fields, for example, have come to be regarded as necessary evils. Recently, in the Morning Post, the Countess Bathurst expressed apprehension lest the Electricity Bill lead to the disfigurement of beautiful parts of Great Britain by overhead electric mains. She says this has already happened in Switzerland and Italy. The average visitor to the continent rarely complains of the unsightliness of the lattice towers supporting overhead wires or even of the open-air transformer substations. A few grumble when they see a row of lattice poles going over the shoulder of a mountain peak, but the inhabitants have got accustomed to it, and, as a rule, regard it with pride. The Countess Bathurst suggests that the mains which form the 'grid' of the Government scheme for Great Britain should be placed underground. But if this were done, the transmission pressure would have to be greatly reduced and the era of cheap electricity would be in the distant future. It is quite possible that when we know more about the causes which make highpressure electricity break down insulating materials, electrical engineers may be able to construct cables to withstand the 135,000 volts which is the standard pressure that will be used. Seeing that many countries are competing for the world's markets, it would be foolish to handicap even temporarily our industries merely for æsthetic considerations. The authorites responsible, however, should bear in mind that 'safety' is not the only consideration, and that the colours of the lattice poles and auxiliary devices should harmonise with their surroundings.

A flight across the Beaufort Sea is now being planned by Mr. G. H. Wilkins. According to Science Service of Washington, he proposes shortly to leave Point Barrow, Alaska, and set a course for about lat. 84° N., long. 100° W., which should take him over the position of Peary's reported Crocker Land. Thence he proposes to cross Ellesmere Island to Etah in Greenland. If the aeroplane is forced to descend on the way, the party hope to be able to return on foot, living on seals during the march. Even if all goes well, Mr. Wilkins points out that there may be considerable delay in his return owing to the poor communications with Etah and Ellesmere Island. Science Service also records a flight made by Mr.

Wilkins and Mr. B. Eielson from Point Barrow on Mar 29 of this year. On that occasion, with fuel for 1400 miles in calm weather, they proposed to fly 600 miles north-west, then 200 miles south, and then back to Point Barrow, thus investigating the southern borders of the Beaufort Sea. Engine trouble caused a forced descent about 550 miles north-west of Point Barrow. A sounding of 'about three miles' indicated that he was north of the continental shelf. The exact position is not given. The flight was resumed, but a second forced landing soon had to be made. Eventually, by drifting with the ice and sledging. they returned to Point Barrow. Mr. Wilkins maintains that, contrary to the belief expressed by Capt. Amundsen and others, there are plenty of good landing places on polar pack.

RECENT acquisitions of the British Museum (Natural History) include the following. The Zoological Department has received a pair of elephant tusks of almost record size, presented by the Government of Kenya Colony. These tusks, which weigh 168 lb and 166 lb and are 9 ft.  $2\frac{1}{2}$  m. and 9 ft.  $2\frac{1}{4}$  m long respectively, were at the British Empire Exhibition, The Department is sharing with the Museum d'Histoire Naturelle, Paris, the specimens collected in French Indo-China by M. J. Delacour and Mr. Willoughby P. Lowe. The British Museum consignment includes the rare carnivore Chrotogale. The most important purchase recently sanctioned by the Trustees is a large fossil amphibian obtained by Dr. B. Dunstan from hard sandstone of Triassic age near Sydney, N.S.W. The specimen, which is about 9 ft. long, is in the form of hollow moulds left after the decay of the bones. It will be possible to take plaster casts from these and to mount them as a skeleton, complete except for a few toe-bones. The specimen is one of the roofed-skull labyrinthodonts and belongs to the group Stereospondyla. Although fragments of fossils of this group have been known for more than a century, there is only one other specimen in which even a portion of the skeleton is associated with the skull, and that is at Stuttgart. During the last century the chalk-pits of Charlton, Northfleet, Lewes, and similar localities in Kent and Sussex, yielded some fossil starfishes, sea-urchins, and remains of fishes in an exceptional state of preservation. The late Mr. James Fox made a notable collection of such objects, and the Museum has now been able to obtain such specimens as it required. The Trustees have authorused the purchase for the Department of Botany of the late Mr. F. W. Payne's collection of 8000 microscope slides of diatoms. The slides are of special interest and value, because only one species is represented on each. The diatoms are mounted whole and also with the frustules separated, and arranged in different ways so that a complete examination can be made.

THE discussion initiated by the Illuminating Engineering Society at the Stationers' Hall on June 14, on the lighting of printing works, served a useful purpose in helping to make known the results

of the valuable investigation conducted by the committee working under the Department for Scientific and Industrial Research. Investigations tracing the influence of conditions on industrial output and efficiency require great care and patience, and the co-operation of the industries concerned is essential in order that conclusions may be willingly accepted. In this case the impartial nature of the Committee and the scientific standing of its members entitle its findings to respect, and the sympathetic co-operation of the Joint Industrial Council for the Printing Trades, the secretaries of which joined in the discussion, has been most valuable. The chief conclusion so far arrived at-that an illumination of the order of 20 foot-candles is necessary for full efficiency in typesetting by hand—is sufficiently striking Probably few composing-rooms receive such a high illumination at present, and a considerable advance may now be anticipated. The conclusion is probably broadly applicable to other forms of fine work, and the lecturer, Mr. Weston, showed that it is economically justified. Numerous points in regard to the best form of lighting in composing-rooms (e.g. whether direct or indirect, general or local, etc.) are still under discussion. From the proceedings at the meeting, it would appear that a combination of moderate general lighting with high local illumination provides the best solution, and this may apply to other exacting forms of work where high illuminations are required.

Much sooner than was expected, some brief accounts of the great Kansu earthquake of May 23 (May 22, Greenwich time) have been received (Times, June 21, 22, and 24), but it seems clear that they come from the outlying zones of damage, not from the central region. At Langchow, the capital of the province, two pagodas were destroyed. The cities of Kanchow and Suhchow were only slightly damaged. So far as is yet known, the city of Liangchowfu, in the northern part of the province, seems to have suffered most. There was an early shock at 4 a.m. (local time), followed at 5.30 a.m. by the principal shock that lasted two minutes and rumed half the city. In this district the telegraph lines were thrown down and many lives were lost.

THE famous Oxfordshire stone circle known as the Rollright Stones, with the outlying cromlech, "The Whispering Knights," has been on the market as part of the estate of Little Rollright Manor. Considered by many archæologists to be older than Stonehenge, no ancient 'temple' is more deserving of the protection of the State, not only within the circuit of the unclimbable iron fence that closely surrounds it, but also by the preservation of a sufficient tract of open land all round, that the locality may not be spoiled by the erection, as at Stonehenge, of distracting and unworthy buildings in the close vicinity of the monument. In "The Cult of the Circle Builders," Mr. E. M. Nelson adopted a unit of length equal to 0 95 of the English foot as the unit employed by the builders of the Circle at Denber's Pasture in Yorkshire and elsewhere The diameter of the Rollight stones is exactly 100 of such feet, and the lay-out of the outlying associated stones appears also to be based on certain proportions, which according to Mr. Nelson were represented by the numbers 3, 7, and an ancient value of  $\pi$ . In any case there is no other monument of the science of the British Bronze Age now extant in the midland or eastern countries than the Rollright circle

THE Rothamsted Experimental Station, Harpenden, will have an instructive exhibit at the Royal Agricultural Society's Show which opens at Newport (Mon ) on July 5. The central portion of the exhibit illustrates the development of types of experiment at Rothamsted from 1843 to the present time, and it shows by means of a precision scale that results now obtained in a single year may be a hundred times as valuable as an experiment carried out twenty years ago Effects of treatment of different plots for grass, mangolds, potatoes, and swedes are shown by actual turves and plants, and the specimens bring out the fact that balance between the different dressings applied to various crops is of essential importance. On the biological side, control work is illustrated, such as parasites of earwigs to combat the earwig pest in New Zealand, and investigations to keep down blackberry, gorse, ragwort, and other injurious plants by means of insects. Results of recent work of the Bacteriological Department of Rothamsted in connexion with the cultivation of lucerne are also included in the exhibit of the Station.

Biology lecturers at agricultural colleges and institutes, as well as teachers in rural schools where the curriculum includes elementary economic biology or nature study, will find that a new series of 'relief plaques' or tablets, lately put on the market, offers an effective aid in the work of giving instruction concerning insect pests and fungoid diseases of farm Most of the tablets measure 12 in, by 10 in, crops though some are larger. Against a black background there is modelled a raised or relief representation of a crop plant of the farm suffering from a fungoid disease or attacked by some well-known insect pest the whole being shown in natural colours. Frequently two, or even more, diseases of the same plant are represented on a single plaque. The models are well executed, and they should be more effective for class demonstration than ordinary pretorial representations of the various pests. Accompanying every plaque is a description of the pest the activities of which are indicated, and of recognised methods of control, written by a member of the staff of the Royal Agricultural College, Circnester. The tablets have been prepared in Germany by the Deutsche Hochbild-Gesellschaft of Munich, and are reported to have been adopted at a number of agricultural educational institutions in continental countries. We understand that an English company is being formed to take up the business of the manufacture and sale of these, and other similar series of educational relief plaques, in Great Britian.

UNDER the Buths and Deaths Registration Act, 1926, which came into force on July I, the registration of still-births by the Registrars of Births and Deaths becomes obligatory. It has long been felt that the vital statistics of Great Britain have been deficient by non-registration of still-births. The Ministry of Health has issued leaflets (Circulars Nos. 802 and 802a), addressed to supervising authorities under the Midwives Acts and authorities carrying out maternity and child welfare schemes respectively, detailing the procedure under, and the principal provisions of, the new Act

In his recently published presidential address to the Quekett Microscopical Club, Sir David Prain recalled the establishment in his first medical school in 1878 of laboratory classes in botany, zoology, and physiology, so that, with the class on histology, there were in two years of study four courses involving to a greater or less degree microscopic work. were assured on the authority of four earnest teachers that it was our duty to be able to use the microscope. . . . No hint, however, was ever given us that to work with the microscope may be a source of pleasure Little wonder that to some microscopic work appeared a disagreeable necessity, that to many it remained a matter of course; and that to only a few was vouchsafed the privilege of penetrating the secret of the Quekett Club." It is still unfortunately the case that few students either in biology or in medicine have penetrated this secret, but perhaps the hint that pleasure may be found in work with the microscope is as rarely given as in 1878.

THE president and council of the Royal Society have recommended Mr. Stanley Baldwin for election into the Society under the special statute which permits the election of persons who, in their opinion, either have rendered conspicuous service to the cause of science or are such that their election would be of signal benefit to the Society.

THE Government of India has invited the Far Eastern Association of Tropical Medicine to hold its seventh Congress in India in 1927, and the Congress will open at Calcutta on Dec. 5. The president is Major-General T. H. Symons, Director-General of the Indian Medical Service, and the general organising secretary, Lieut.-Col. J. Cunningham, I.M.S., from whom all information may be obtained at the Pasteur Institute of India, Kasauli, Punjab.

WE understand from A.S.L.I.B. (the Association of Special Libraries and Information Bureaux), 38 Bloomsbury Square, London, W.C.1, that the "Directory of Sources of Specialised Information," which the Association is preparing under the editorship of Mr. G. F. Barwick, is approaching completion. Mr. Barwick would like especially to include some more collections in the possession of private individuals.

At the Royal Statistical Society's annual general meeting held on June 21, it was reported that the

number of fellows on the roll is now 1056, and shows a small increase over last year. In the course of the proceedings a proposal was made that the existing letters, F.S.S., denoting fellowship of the Society, should be changed so as to include an indication of the status of the Society as a Royal Society. The alteration was opposed on behalf of the Council, and after some discussion the motion was withdrawn. Viscount D'Abernon was elected president for a second year, and the other officers of the Society were also re-elected

THE Royal Photographic Society of Great Britain will hold its seventy-second annual exhibition in September and October of this year. This is the most representative exhibition of photographic work in the world, and comprises the recent achievements of photography, both pure and applied. It is desired to make the Scientific and Technical Section as representative as possible, and with this end in view exhibits are invited, which may comprise apparatus, models, prints, diagrams, transparencies, or any other form of record illustrating the applications of the photographic method to biology, botany, mineralogy, microscopy, geography, geology, spectroscopy, photometry, engineering, colorimetry, textiles, etc. Exhibits should be sent before Aug. 13, addressed to the Royal Photographic Society, 35 Russell Square, W.C.1. All communications should be addressed to the honorary secretary of the Scientific and Technical Group, Olaf Bloch, 35, Russell Square, W.C.1.

The issue of the Scientific American for May contains an account of the survey of a portion of Alaska by means of three all-metal aeroplanes of amphibian type with 7 officers and 40 men from the United States Naval Air Station at San Diego. More than 40,000 square miles of rugged unexplored country was surveyed, a fourth of the survey being completed in a fortnight. A lake nine miles long and four wide was discovered at an altitude of 1500 feet, and will be used to furnish 100,000 electrical horse-power. Extensive forests of spruce, pine, and hemlock were also found, and a paper mill is to be established in the neighbourhood.

THE Report of the Museum at Valletta, Malta, for 1925-26, records the exploration of many archæological sites; the handle of a neolithic clay vase representing a ram's head is called by Prof. Zammit "the most important find of the year." The material illustrating local natural history, transferred from the University Museum in 1924, has now for the most part been placed provisionally on exhibition, and a summary catalogue of the constituent collections, as well as of recent accessions, is contributed to the report by Mr. Despott and should prove useful.

THE. Section of Geodesy of the Geodetic and Geophysical Union has recently published No. 9 of the Bulletin Géodésique, in advance of the still unpublished Nos 7, 8. Its contents are partly in English, partly in French. Besides a useful bibliography of recent publications, and an international

chronicle of geophysical organisation and work in various countries, it contains four articles of general The first is a reprint of Dutton's address at Washington in 1889 on the contractional and isostatic hypotheses in physical geology. Two other articles deal with new geodetic measurements in Poland and France, while the last article describes a portable automatic tide gauge produced by the US. Coast and Geodetic Survey.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—Research chemists and a research physicist at the Building Research Station, Garston, Watford-The Secretary, Department of Scientific and Industrial Research, 16 Old Queen Street, S.W.1 (July 11). A lecturer in the zoology department of King's College, London--The Secretary, King's College, Strand, W.C.2 (July 12). A secretary and treasurer of the Rowett Research Institute—The Secretary, Rowett Research

Institute, Bucksburn, Aberdeen (July 12). A bacteriologist in connexion with the Dairying Research Division of the Ministry of Agriculture for Northern Ireland—The Secretary, Ministry of Agriculture for Northern Ireland, Wellington Place, Belfast (July 15). An assistant lecturer in geology in the University of Manchester -- The Registrar, University, Manchester (July 16). An evening lecturer in philosophy and logic at Birkbeck College-The Secretary, Birkbeck College, Fetter Lane, E.C.4 (July 16). An assistant in the department of economics of the South-Eastern Agricultural College, Wye, Kent-The Principal, South-Eastern Agricultural College, Wye, Kent. A half-time demonstrator and half-time research assistant familiar with X-ray apparatus and its use in crystallography, and a research assistant familiar with the chemistry and physics of photosynthesis, in the department of physics of the University of Toronto -Prof. J. C. McLennan, Athenaum Club, Pall Mall, S.W.1.

### Our Astronomical Column.

COMET PONS-WINNECKE. - Recent observations. both visual and photographic, indicate a very definite central condensation, 10" in diameter or less, permitting accurate measures to be made. According to usual views of comets, this indicates a welldefined meteoric cluster, not exceeding 250 miles in diameter. It is rather a puzzle how they have maintained this compact regular formation through at least 108 years, in view of repeated large perturbations by Jupiter. It suggests that some force other than gravitation may help to keep the constituents together.

The comet was seen with the naked eye on several occasions by those who knew exactly where to look for it; it could be seen in the telescope before the close of twilight. Since its distance is only about a quarter of that of Eros in 1931, it should be possible to derive a good value of the solar parallax, provided that nearly simultaneous observations are available from the southern hemisphere The distance on the night of June 26-27 was about 3,600,000 miles. According to a bulletin dated June 4, issued by Science Service of Washington, there is only one case known of a nearer approach of a comet to the earth. That is the comet 1770 I, known as Lexell's, which passed within 1,400,000 miles of the earth on July 1, 1770. Its coma then appeared 2\frac{1}{2} in diameter (Chambers, "Story of the Comets," p. 87).

The motion of comet Pons-Winnecke was so rapid that on a photograph with the Greenwich Astrographic taken about 1h on June 23, with 3 minutes exposure, it appeared as a narrow faint trail more than a millimetre long.

THE GREAT PERSEID SHOWER OF METEORS.—Mr. W. F. Denning writes: "This important stream commences at the end of June or beginning of July. It is desirable to ascertain the dates when the first and last members of the display are visible. From a discussion of thousands of recorded paths, between about June 21 and Sept. 10, I think that the limiting dates are June 25 and Sept. 5, a period of 72 days. But in consequence of the many feeble contemporary systems in play with radiants in the same region of the heavens, it is difficult to decide with absolute safety on the exact period over which true Perseids continue to fall. It would be a good plan to arrange simultaneous watches by a number of trustworthy

observers Meteors doubly observed yield radiants which are not affected with the same doubts as an object seen by one observer only. A meteor may be directed from the radiant of the Perseids and vet belong to another centre, whereas multiple records of the same object must give the correct radiant if the data are accurately recorded.

"The return of the Perseids this year takes place amid bright moonlight. The meteors, however, are often so bright and abundant on Aug. 11 and 12 that they well repay watching even when the moon is present."

The Spectrohelioscope. -- An article by Lee McCrao in the Scientific American for March gives an illustrated description of Prof. Hale's spectrohelioscope, which accomplishes visually the same work that the spectroholiograph does photographically (see also Nature, July 3, 1926, Supp. p. 1). It is not essentially new; the earliest spectroscopic observations of the solar prominences were made visually, and the method of the oscillating slit, which is the main feature of Prof. Hale's instrument, was tried in those days. But long experience has so greatly improved all the accessories that the method is now much more effective.

The article points out the many advantages of the visual over the photographic method; the photograph can only catch a particular aspect, whoreas the visual method, like a cinema film, shows the progress of events. Its action is more rapid than the photograph; further, it can pick out the regions of the sun where interesting developments are in progress, and follow them through their different stages.

Another advantage is that cruptions occur which change the wave-length of the line owing to Doppler effect. A record of these would be lost on the photograph, but can be obtained visually, since there is a device for altering the position of the slit. Knowledge has already been gained in this way regarding the nature of the whirling motion that occurs round sunspots. It is hoped to establish more accurately the relation between solar cruptions and magnetic storms on the earth.

Prof. Hale is trying to produce a simpler and cheaper form of the instrument, and hopes that it may lead to a more general and continuous watch

on the sun for detecting outbursts.

#### Research Items.

CELTS FROM KNOLE PARK, SEVENOAKS .-- Mr. J. P. T. Burchell contributes to Man for June a further note on the unorthodox association of polished celts and stemmed and barbed arrowheads from Knole Park. The celts, which have thin butts and pointed oval section, according to the Scandinavian chronology should belong to the pre-Dolmen period, but in England they have been found, as at Bexley Heath, in association with celts having a thin butt and square sides, and must be considered as having survived well into the Dolmen period. The celt with thick butt characteristic of the second Dolmen period in Scandinavia was not adopted in England. At Seamer Moor, Yorkshire, celts with thin butt and pointed oval section were found with expanding edges and incurved sides, together with kite-shaped arrowheads. In the passage graves of Scandinavia occur narrowbladed diggers, shaft-hole axes with expanding cutting edges and incurved sides, together with hollow-based arrowheads. It is suggested that some of the artefacts of the passage-grave period in Scandinavia and Britain are copies in flint of existing metal types of more southern lands The last period of Britain, the third phase of the Dolmen cult, is definitely of the Bronze Age, though the use of the metal is still deferred in Scandinavia. The Knole Park settlement, with its stemmed and barbed arrowheads typical of the encolithic period, cannot be much earlier than the times of the round barrows. The celts indicate that the settlement was occupied by descendants of the pre-Dolmen period and that they were under the influence of an alien race.

VERTICAL DISTRIBUTION OF MARINE MACROPLANKTON.—In a fifth paper on this subject (Jour. Marine Biol. Assoc, vol 14, No. 3, 1927, pp 557-608) dealing with the catches of a stramm ring-trawl, Mr. F. S. Russell gives particulars regarding the animals other than young fish, which have already been dealt with. The hauls were made at serial depths during the daylight at intervals between April and August 1926 and give a valuable series of records for many important plankton species. In general, Mr. Russell finds that most species have an optimum level in the water in which they live in the daytime, though this may vary according to weather and other conditions in ways not yet fully understood.

PHILIPPINE HYDROIDS.—The late Prof. C. C. Nutting reports (U.S. Nat. Mus. Bull. 100, 1927) on the hydroids collected by the U.S. Fisheries steamer Albatross in the Philippine region. Hydroids were taken at 58 of the 575 dredging stations reported for that cruise, which does not indicate an extraordinarily rich hydroid fauna. The collection represents 10 families, 27 genera, and 54 species, and affords many new records of species not hitherto found in the Philippine region. Prof. Nutting remarks on the relative scarcity of gymnoblastic forms, there being but three species belonging to this group, and one of these, the giant tubularid Branchiocerianthus imperator, was dredged outside the Philippine area in Japanese waters. Twenty-six species, almost one half of the total, belong to the family Plumularidæ. The author adds some remarks on the recent multiplication of names and the breaking up of old genera by Stechow, which tend in his opinion to confuse the situation, and he expresses his own preference for a conservative course m nomenclature.

Hybridisation and Variability.—'New Lights on Evolution' is the title of an address by Prof. E. C. Jeffrey (Science, May 13, p. 458), the burden of

which is an exposition of his well-known view that polymorphic genera of plants and animals are all hybrids. While formerly holding that hybrids were of no significance for evolution, he now appears to have adopted Lotsy's view that natural hybridisation is the only cause of variability. With all the ardour of a convert, he even maintains that Drosophila melanogaster is of hybrid origin, notwithstanding the abundant contrary evidence. The widespread occurrence of hybridism in flowering plants is recognised by many, but probably few would venture to see in it the sole effective cause of variation Similarly, the author believes previous crossing to be the cause of parthenogenesis, but he omits to consider Artenna salina and its tetraploid parthenogenetic variety in this connexion.

Tanaodon: a new Pelecypod Genus —A most remarkable pelecypod from the Middle Devoman of China has just been described by Mr. Edwin Kirk (Proc. U.S. Nat. Mus., vol. 70, art. 12). Externally it somewhat resembles Megalodon, and the author places it in the Megalodontida. The hinge, however, is strikingly different from that of any hithertoknown bivalve. The teeth form a series of elongate ridges disposed fan-wise, radiating from the umbo, and it is difficult to distribute them satisfactorily into cardinal and lateral. The author considers that eight may be reckoned as cardinal and three (or more) as posterior lateral. His figure shows thirteen of these ridges in all. Another interesting feature of the shell is the very prominent external lumbonopostero-ventral ridge, which at its point of origin at the umbones is raised into a sharp keel but becomes less and less prominent as it passes outwards. It reminds one of the similar keel in Hemicardium.

GRAVITY SURVEY OF KWANTO.—The recent issue (No. 2) of vol. 4 of the Japanese Journal of Astronomy and Geophysics is wholly devoted to a report of a gravity survey, using an Eotvos variometer, of the Kwanto district, which suffered a great earthquake on Sept. 1, 1923. The district has since been investigated along many lines of geophysical research: land and hydrographic surveys have shown that the vertical displacements of the bottom of the Bay of Sagamı, resulting from the earthquake, are more than a hundred times those of the land. In the present gravity survey, by N. Kumagai, 76 points were occupied, and the observations are carefully discussed and corrected for various sources of error, though further corrections are to be embodied in a later report. Unfortunately, few gravity observations dating from before the earthquake are available for the district, so that the observations of the present survey cannot be used to infer changes of density distribution resulting from the earthquake.

Positive Thermions.—The May number of the Journal of the Franklin Institute contains an account by Dr. C. H. Kunsman of the 'iron catalyst' source of positive ions of the alkalı and alkalıne earth metals. Its great advantage is that the mixture from which the ions are produced can be mounted on a filament and used in a high vacuum. The source is, moreover, steady and not readily exhausted, whereas most of the older methods of producing positive ions either required the presence of gas or gave an emission which fell off rapidly with time. Dr. Kunsman has been able to show that the temperature variation of both the positive ion current and the electron current from a given specimen is in accord with the Richardson

equation, and that the energy needed to remove a positive ion from the surface is consistently less than that required by an electron. It seems probable that metal diffuses to the surface in much the same way as thorium does in the heat treatment of a thoriated filament. The ions have been analysed at Princeton by means of the mass spectrograph and have been shown to be singly charged atoms, and they have already been applied in the same laboratory to the study of the secondary emission of electrons when metal plates which have been thoroughly freed from gas are bombarded with positive ions.

26

THE BURNING OF CARBON DISULPHUDE.—It has been shown by A. G. White that the addition of small quantities of the vapours of ether, benzene, acetone, and acetaldehyde to mixtures of carbon disulphide and air causes a pronounced contraction in the range of flame propagation, especially at the lower limit. The results of further work on this subject are published in the Journal of the Chemical Society for April 1927. The present results are in general agreement with former work, and indicate that the added substance appears to act in three ways. (1) it alters the thermal constants of the mixture; (2) it alters the percentage of oxygen in the mixture, (3) it produces a specific catalytic effect. Of these, the catalytic effect is the most important and varies enormously from substance to substance. The order of efficacy of certain substances in preventing the propagation of flame at the limit in mixtures of carbon disulphide and air given by White differs from that found by Dixon.

DECOMPOSITION OF COAL.—Technical Paper No 16 on fuel research (London · H.M. Stationery Office. 9d. net) records observations by J. G. King and R. E. Willgress, of the Fuel Research Station, on the "Primary Decomposition of Coal" The temperatures of initial decomposition of fuels were found to range from 180° C. for peat to 215°-245° C. for bituminous coals. For these coals the temperature of initial decomposition appeared to increase with decrease in carbon content, and to increase with increasing oxygen The evolution of moisture is a gradual process, but the first acceleration of moisture evolution coincides with the appearance of oil vapour. The temperatures observed are somewhat lower than those recorded by previous workers, and deserve consideration in connexion with all processes or researches involving heat treatment of coal in the region of 200°-300° C., in which the possibility of chemical change must never be overlooked.

Dopes and Detonations.—The second report on dopes and detonations (Aeronautical Research Committee: Reports and Memoranda, No. 1062 (E 23). London: H.M. Stationery Office, 1927 1s. 3d. net) has recently been published. The investigation which the report describes has included an experimental and theoretical study of low temperature oxidation of liquid fuels in air, in conjunction with engine experiments to determine the relationship between detonation and observed chemical action. The conclusion drawn from the experiments is that detonation in paraffin fuels and ether is due to the accumulation of peroxides in the nuclear drops during rapid compression. These drops ignite simultaneously when the detonation temperature of the peroxide is reached. The amount of peroxide formed would not in itself be sufficient to cause the detonation observed, but acts as a primer by simultaneous ignition of the nuclear drops. The metallic dopes act by reducing the peroxides as fast as they can be formed, and preventing their accumulation, thus delaying the ignition of the drops.

'HAVEG'-In the Chemiker-Zeitung for May 11 there is an account of the use of 'Haveg,' an artificial resmous material like bakelite, for the manufacture of large pieces of chemical apparatus without the use of an iron-core or other reinforcement. Vessels can be constructed in one piece and without seams, up to 2.6 metres in diameter. The thickness of the walls varies from 10 mm. to 40 mm., and the vessels can withstand sudden alterations in temperature up to 130° C. Since the specific gravity lies between 16 and 18, the apparatus can be handled easily; more-over, breakages can be repaired inexpensively. During the hardening process the resin shrinks considerably, so that some difficulty is experienced during manufacture, if it is desired to combine it with metal. This difficulty has been overcome by constructing the inner vessel of perforated sheet metal, the perforations of which become filled with the resin, which when hard forms knobs or studs serving to bind the outer casing to the inner one.

RADIOLOGICAL APPARATUS — The latest (1927) edition of Messis Newton and Wright's catalogue of apparatus for radiology describes in a brief but quite adequate way the various types of apparatus they make for radio-diagnostic, radio-therapoutic and X-ray research purposes. The closed circuit transformer has been developed for many years by this firm, and they are now able to build these machines for 250 kilovolts rectified three-phase output, giving practically continuous high-tension current without the introduction of condensers. Considerable prominence is given among the illustrations to the types of 'Metalix' tubes which are now available for medical and other purposes. This tube is, we understand, becoming largely used in medical work, its handmess of form being a great feature in its favour.

ELECTRODE STEAM GENERATORS. The importance of having a uniform load on an electric power-station is well known to electrical engineers. If there is a large demand for a short period every day, the station must have sufficient plant to earry over the peak load, and this means that a number of machines are lying idle during nearly all the day, and so the overhead costs are large compared with the revenue Engineers do their utmost, therefore, to secure a level load. For example, they often supply energy at a much cheaper rate during the night when the demand is small. take advantage of this, electrode boilers are sometimes used which store the electrical energy delivered during the cheap period of supply as heat, either by heating water or converting it into steam. In the Bulletin for March of the Oerlikon Co. of Zurich, there is a description of electrode steam generators for electric pressures varying between 3000 volts and 8000 volts. One of the hospitals in Basle obtains steam and hot water for the kitchen and the laundry in this way. Two similar boilers each for 1000 kilowatt, 6000 volts, have been ordered for an installation in Great Britain. In Switzerland, where sometimes only a limited amount of electric power obtained from waterfalls is available, it is a boon to use these devices and so eliminate chimneys and smoke and avoid the necessity of coal storage room. The cost of maintenance of these electrode steam generators is very small. The equipment works as a star connected plant, with the boiler itself acting as the neutral point. It is therefore safe to have in a building. Tests on a hightension boiler for 1200 kilowatts and 6400 volts have shown that the efficiency of the boiler can be as high as 98 per cent. We think that these electrode steam generators can in many cases be advantageously

### The Influence of Water in Physical Change.

PROF H. E. ARMSTRONG has long insisted on the view that chemical action is a species of reversed electrolysis and that an electrolyte, generally water in terrestrial systems, is a sine qua non for chemical action. Whether we should regard modifications in the 'molecular' weights of a liquid, alteration in the constants' of the Van der Waal's equation of state for a vapour or gas, change in the surface tension or vapour pressure of a liquid, all due to association or dissociation, as caused by the operation of physical or chemical change, might be debated by

At least three different types of union can readily he recognised, such as the cluster of polar molecules round charged ions, the association of molecules which are either dipolar or possess poles of a higher order, and thirdly, the definite electrovalent bond in which one or more electrons have been definitely transferred from the orbit of one atom to another, chemical union is certainly not restricted to the third class. In the second there appear to be all graduations in strength of union between polar molecules with increasing mutual distortion of the valence electron orbits and consequent alteration in the electric moments of the molecules. The enoimous chemical reactivity of charged ions as well as the influence of water on chemical reactions indicates that water may function not only as an electrolyte but also in virtue of the fact that it consists of molecules of high

electric moment; the latter may promote, as observed

by Sir J. J Thomson, the formation of clusters or

addition compounds in reaction, and also render more

polar, and in consequence more reactive, the molecules

clustered in the primary addition compound

Similar conclusions as to the necessity of stages in compound formation may be drawn from a consideration of the phenomenon of adsorption as well as the energies of 'catalysed' and non-catalysed reactions. It is clear that such compound formation included in the term 'association' is not necessarily an electrolytic process as generally understood, for in at any rate simple systems it is no more than the clustering of polar molecules around an ion, and, in somewhat more complicated cases, the effect of mutual attraction of molecules possessing definite electric moments being either dipolar or polar of a higher order. Such considerations involve inclusion of both mutual and interaction of ions and of polar molecules each possessing finite electric moments, as well as of reactions

involving two electrodes and an electrolyte, in our system of chemical reaction mechanism

The delivery and publication of the presidential address to the Chemical Society on Mar. 24, by Prof H B. Baker, represents this further stage in the experimental development of the idea associated with the action of water in chemical change ("Experiments on Molecular Association." Jour Chem. Soc (April), 949; 1927). Since the president was one of the first to investigate experimentally the functions of water in chemical change in gas reactions, so it is only to be anticipated that he would be the first to investigate its functions in physico-chemical changes involved in molecular association

Prof Baker has shown that all the liquids which he has examined may be regarded as analogous to an associable gas such as introgen dioxide, association increasing with decrease in temperature. The position of equilibrium in liquids is thus influenced by alteration in temperature, and the rate of attainment of the new equilibrium is greatly affected by the presence of catalysts, of which water is one of the most important. The necessity for some type of catalyst is clear when the thermal energies involved are considered. Thus the mean thermal energy at 0° C of a molecule is some 0 035 volt, the process of disintegration of a binary complex of two hydrogen molecules requires only some 0 01 volt, but for vaporisation of liquids such as liquid bromine, benzene, or water, energies equivalent to 0.3 to 0.5 volt are required Hydrogen complexes evidently would be rapidly broken up by thermal agitation alone at ordinary temperatures, but the destruction of complexes in these liquids, although possible by thermal agitation, will evidently proceed at a slow rate in the absence of a catalyst necessarily polar in character.

The existence of such complexes in solution and the gradual transformation of one type into another has been amply demonstrated by Prof. Baker in numerous experiments which have been considerably extended in this address. He has shown, inter alia, by vapour pressure and surface tension measurements, that the rate of attainment of equilibrium is affected not only by water but also by solid catalysts such as charcoal, platinum black, and thoria. If these catalysts were actually as dry as the liquids employed, we note again further evidence in the process of adsorption for the operation of forces causing reaction in the absence of water.

Eric K. Rideal.

### Archæology in Greece.1

If this issue of the "Annual of the British School at Athens" belies its name by covering two yearly sessions, it is nevertheless true to its pre-War tradition both in the interest of its contents and the dignity of its appearance. First in importance must be placed the report of the excavations of two seasons, 1924 and 1925, at Sparta. In both years the main work was concentrated on the site of the theatre, where considerable portions of the stage and orchestra have been cleared and trials made in the cavea. This section of the work is described by the Director of the School, Mr. A. M. Woodward: the most interesting part of his description is that which deals with the scenae frons and the difficult problems connected with it. He shows that the cavea is a Roman construction, probably of Augustan age, doubtless on the site of an earlier and much smaller theatre. The evidence for

<sup>1</sup> "The Annual of the British School at Athens," No. 26, Sessions 1923-24, 1924-25. Pp. viii+392+22 plates (London: Macmillan and Co., Ltd., n.d.) 63s. net.

the date of the stage-buildings is less clear, for remains of several periods exist, the earliest of which may possibly be earlier than Augustus. The inscriptions from this site, fully published here by Mr. Woodward, are both long and important, for the marble facing-blocks of the east parados-wall of the theatre at its west end literally formed a single inscribed monument.

The other portion of the site attacked was the Acropolis, more particularly the area between the Hieron of Athena Chalkioikos and the retaining wall of the cavea of the theatre. Here a mixed deposit of various dates was cleared which yielded some of the best finds made during the excavations. The most important are the remains of a marble statue, slightly larger than life size, of a bearded warrior wearing a helmet with cheek-pieces decorated each with a ram's head. The arms are lost, but otherwise the statue is complete to the waist. The section in which Mr. Woodward dates this statue to about 480-470 B.C. and seeks to demonstrate that the subject is no other

than the hero of Thermopylæ, is among the most

interesting in the volume.

Messrs. Casson and Heurtley write on the excavations which the British School has for several years past been conducting in the mounds of Macedonia. The former describes a burnal mound at Chauchitsa with numerous interments of the iron age, beginning about 1150-1100 B.C., and the latter classifies and describes pottery picked up on mounds in western Macedonia and west Chalcidice.

It is a far cry from these prehistoric finds to the Finlay Library, some of the contents of which are described by William Miller in an article which is very attractive reading. The other contents of the volume well indicate how wide is the range of the School's activities and those of its students, past and present. Mr. Lawrence writes on Hellenistic sculpture from Rhodes, and Miss Lamb on stamped pithos fragments in the collection of the School, mostly from Melos. Mr. Tillyard discusses the difficult problem of the signature or Martyria in the Byzantine modes and its relation to the cadence; Mr. Seltman deals with the early cult of Eros in Athens and its representation in art, and Mr. Tod makes an invaluable contribution to Laconian epigraphy by giving a list (with references) of inscriptions omitted from the Corpus, or published since its appearance, and by supplementing its bibliographies.

### University and Educational Intelligence.

BIRMINGHAM.—The degree of D.Sc. in chemistry has been awarded to the following: John Alfred Valentine Butler, for numerous papers on "Studies in Heterogenous Equilibria"; and Harold Archibald Scarborough, for papers on "Saponification and Properties of Mixed Solvents."

LONDON.—Sir William Beveridge has been re-elected

vice-chancellor for the year 1927-28.

The title of emeritus professor of anatomy in the University has been conferred on Prof. Edward Barclay-Smith as from the end of the session 1926-27, when he retires from the University chair of anatomy

tenable at King's College.

The following doctorates have been conferred: D.Sc. in Chemistry on Mr. F. H. McDowall (University College), for a thesis entitled "Constituents of Myoporum lætum Forst (The 'Ngaio')"; Mr. I. R. McHaffie (University College), for a thesis entitled "The Effect of the Presence of an Indifferent Gas on the Concentration and Activity of a Vapour in Equilibrium with a condensed Phase or System of Condensed Phases"; Mr. S. O. Rawling (University College), for a thesis entitled "The Sensitivity of Photographic Emulsions"; and Mr. F. Tattersfield (Rothamsted Experimental Station), for a thesis entitled "The Relationship between the Chemical Constitution of Overenic Co Constitution of Organic Compounds and their Toxicity to Insects''; D.Sc. in Geology on Mr. S. W. Wooldridge (King's College), for a thesis entitled "Contributions to the Study of the Structure, Stratigraphy, and Geo-morphology of the London Basin"; D.Sc. (Engineering), on Mr. Bernard Hague (Imperial College—City and Guilds College), for a thesis entitled "Studies in the Theory of the Magnetic Field in Dynamo-Electric Machinery"; D.Sc. in Physics on Mr. J. W. T. Walsh, for a thesis entitled "The Theory of Luminescence in Radioactive Luminous Compound," and other papers.

A University postgraduate travelling studentship has been awarded to Dr. R. Purcell (Imperial College Science and Technology—Royal College of Science), who proposes to carry on chemical research at the University of Amsterdam under Prof. A. Smits, and to visit German universities.

The purchase for the sum of £525,000 of the Bloomsbury site by the University from the Duke of Bedford has been completed. The site, including roads, comprises about 111 acres, bounded by Montague Place, Malet Street, Gordon Square, Woburn Square, Upper Montague Street, and Russell Square. £400,000 has been provided by the donation from the Rockefeller Foundation and £125,000 is derived from a Special Government Grant in respect of improved accommodation for the University.

During the celebrations at Louvain on June 28 and 29 to commemorate the five hundredth anniversary of the foundation of the University, the honorary degree of D Sc. was conferred on Prof. E. G. Coker, professor of civil and mechanical engineering, University of London, University College.

A vacation course for open-air work in geography, regional survey, geology, botany, and sketching will be held in Snowdoma on Aug. 19—Sept. 2. The centre will be Llanberis, and excursions to selected parts of Snowdoma will provide training in all branches of open-air work. Further particulars may be obtained by sending a stamped addressed envelope to Mr. Valentine Davis, Cheshire County Training College, Crewe.

The Royal Commissioners for the Exhibition of 1851 have made the following appointments to Senior Studentships for 1927, the recommending bodies being indicated in brackets after the names. Mr. R. C. Blackie (University of Liverpool), for research in geology. Miss P. A. Hicks (University College of South Wales and Monmouthshire), for research in botany; Mr. R. Hill, for research in bio-chemistry, Mr. D. C. Rose, for research in physics, and Mr. L. H. Thomas, for research in theoretical physics (University of Cambridge); Dr E. J. Williams (University College of Swansea and the Victoria University of Manchester), for research in physics.

Post-War depreciation in the value of available funds has been keenly felt by those responsible for important libraries. The initial cost of books has largely increased, and the cost of binding has been more than doubled. Such expenditure, essential if the institution is to be up-to-date, presents therefore a difficult problem; and m a library such as that of University College, London (which ranks in point of size third among the libraries of London and fifth among the university libraries of the Empire), the problem takes on a very serious aspect. Already the University Grants Committee has indicated the inadequacy of present library provision (see also NATURE, May 21, p. 733). So insufficient are the available funds at University College that a capital fund of £24,000 is being sought. Without it the usefulness of the library will be seriously impaired, not only by lack of means for purchase and binding, but also because of the difficulty of printing subject catalogues and other aids which are almost indispensable to the scholar. It is to be noted, too, that £7000 was recently expended on structural alterations to the Science Library, which is also absorbing part of a special grant of £10,000 for its completion. While the libraries are arranged primarily to meet the needs of staff and students, it should not be forgotten that they are available for all genuine students who make application, and that members of the British Association and of the Geologists' Association, whose libraries form part of the Science Library, have the right to use that Library. All interested are invited to co-operate in providing the required sum of £24,000.

### Calendar of Discovery and Invention.

July 3, 1769.—Arkwright's famous patent for spinning by rollers was taken out on July 3, 1769, a few months after Watt's still more famous patent on the separate condenser for steam engines. A barber by trade, Arkwright became interested in the cotton-spinning problem in 1766 when thirty-five years of age, and his first machine was exhibited in the old Grammar School at Preston two years later His machine of 1769 is preserved in the Science Museum, South Kensington. There are four rollers in pairs, the top rollers being covered with leather, while the lower rollers are fluted, the several pairs being weighted to ensure contact. His roller drawing principle exists to-day.

July 4, 1840.—The first steam vessel to carry the mails between England and America, and the first vessel of the famous Cunard Steamship Company, the s.s. Britannia, sailed from Liverpool on her maiden voyage on July 4, 1840, and reached Boston in 14 days 8 hours. She was built of wood and driven by paddles, and could accommodate 115 passengers

July 5, 1639.—The incident related of Galileo watching the lamps swinging in Pisa Cathedral dates back to 1582. Many years afterwards, on July 5, 1639, in a letter he suggested the use of a swinging pendulum for astronomical purposes, and about the same time an arrangement was devised and set out on a drawing, for driving a pendulum by weights.

July 6, 1787.—On July 14, 1787, John Wilkinson, the famous Shropshire ironmaster, wrote: "Yesterday week my iron boat was launched. It answers all my expectations and it has convinced the unbelievers who were 999 in 1000. It will be a nine days' wonder, and then be like Columbus's egg." This iron canal barge, the first of all iron boats, was followed by several others, but iron as a constructive material did not come into general use for half a century.

July 7, 1879.—Among the most important observa-tories of the Far East are those of Zikawei, near Shanghai, and Manila, founded by the Society of Jesus, which alone among the great religious orders has been famous for its scientific work. The Manila observatory was first situated at Ateneo, and then at Ermita, and was founded in 1865 by Father Faura, S.J, who after some years of meteorological work, on July 7, 1879, predicted that a typhoon would pass The event justified his warning. over North Luzon This was the first time that the existence, duration, and course of a typhoon had been predicted in the Far East. Father Faura's subsequent work proved so valuable that the merchants subscribed for its continuance, and with the connexion of Manila and Hong Kong by submarine cable came the beginning of the system of weather forecasts which has proved such an immense boon to shipping in the China Seas.

July 8, 1814.—One of the visitors to Paris soon after the fall of Napoleon was Edward Stanley, Bishop of Norwich, who, writing to his wife on July 8, 1814, gave an interesting account of his visit to the Jardin des Plantes, where "everything is arranged in such order that it is almost impossible to see it without feeling a love of science; here the mineralogist, geologist, naturalist, and entomologist may each pursue his favourite studies unmolested. Here, as everywhere else, the utmost liberality is shown to all, but to Englishmen particularly, your country is your passport."

July 9, 1908.—Following up the methods of Sir James Dewar, Kamerlingh Onnes, of the University of Leyden, liquefied helium, the only remaining gas that had not been coerced into that state, on July 9, 1908.

E. C. S.

Societies and Academies.

LONDON.

Royal Society, June 23.—J C McLennan and J. H. McLeod. On the wave-length of the green auroral line in the oxygen spectrum. In 1925, McLennan and Shrum found a line in the spectrum of highly purified oxygen of wave-length  $\lambda$  5577·35 $\pm$ 0·15, and provisionally identified it with the green auroral line. Reinvestigation with a Fabry-Perot interferometer now determines the wave-length of this line as 5577·341 $\pm$ 0 004 Babcock's value for the wavelength of the auroral line being 5577 350 $\pm$ 0·005, there would thus seem to be no doubt as to the identity of the lines. Apparently oxygen as well as introgen is present in those regions of the upper atmosphere whence the auroral light is transmitted.

A. Caress and E K. Rideal: The combination of introgen and hydrogen activated by electrons. A study of the combination of nitrogen and hydrogen to form ammonia in a triode valve has been made. Hydrogen atoms formed by thermal dissociation at a hot tungsten emitter combine with nitrogen at platmum and nickel surfaces to form ammonia. Hydrogen atoms excited by collision with ca 13-volt electrons react with molecular nitrogen in the gas phase to form ammonia. In the absence of hydrogen atoms (by using a mixed barium calcium oxide emitter) no ammonia is observed until a voltage of 17 volts is attained, and a further rise in rate of formation occurs at 23 volts. These two rises are attributed to the chemical reactivity of  $N_2^+$  and  $N^+$ . Ammonia seems to be produced by interaction of  $N_2^+$  and  $N^+$  with hydrogen to form primarily excited hydrogen atoms. The electron-efficiency of ammonia-formation from nitrogen ions is at least one ammonia molecule produced for the passage of four electrons; in the case of excited hydrogen atoms the efficiency appears to be even higher.

J. F. Lehmann and J. H. Osgood. The total ionisation due to the absorption in air of slow cathode Electrons ejected from a hot tungsten filament were accelerated to an anode, by a potential difference of 200 up to 1000 volts and a portion passed through a carbon capillary into an ionisation chamber. The electron current entering the chamber, and the positive ion current due to the absorption of these electrons, were measured alternately. Ratio of ionisation current to electron current gave average ionisation per electron. Using an electron beam of given initial energy, ionisation per electron is approximately proportional to pressure of absorbing air, provided this pressure was less than a certain 'critical pressure.' For greater pressures, ionisation per electron was constant. The magnitude of the critical pressure was determined by the initial energy of the electron beam. Ratio of ionisation current to electron current, at pressures greater than critical pressure, represents average total ionisation due to complete absorption of an electron. This is directly proportional to initial energy of electron, and the ratio, initial energy of electrons/average total ionisation per electron, gave average energy expenditure associated with the formation of a pair of ions. This average per ion pair was 45 electron-volts, whereas the ionisation potential of

air is 17 volts.

J. F. Lehmann. The absorption of slow cathode rays in various gases. A homogeneous beam of electrons of definite initial energy was introduced into an ionisation chamber. For complete absorption of the electron beam the average ionisation per electron was directly proportional to the energy of the electrons, the constant of proportionality varying markedly

from gas to gas. The ratio, initial energy of electron/ average ionisation per electron for complete absorption, determined the average energy expenditure associated with the formation of a pair of ions. This ranged from 31 electron-volts per ion pair in helium to 45 electron-volts per ion pair in air, nitrogen, and carbon dioxide. The efficiency of ionisation as defined by the ratio, ionisation potential/average energy expended per ion pair, was, in helium 0.78, argon 0.46, hydrogen 0 43, nitrogen 0 38, and carbon dioxide 0.32. Thus much of the initial energy of the electron was expended by processes other than separating the

molecule into positive and negative ion.

W. T. Astbury. A simple radioactive method for the photographic measurements of the integrated intensity of X-ray spectra. A simple photometric arrangement is described in which the negative is replaced by a carbon print and the measurements are carried out by means of α-rays and an α-ray electroscope. This radioactivity photometer has been applied to the investigation of the intensity distribution in X-ray crystal photographs. As a preliminary test the apparatus was used to find the intensity ratio,  $\operatorname{Cu} K_a/K_{\beta}$ . In X-ray photographs of the (muscovite) mica cleavage plane it was found that, 1st order  $\cdot$  2nd order  $\cdot$  3rd order  $= 66:31\cdot100$ , and that the intensity ratio is  $6\cdot 2$  The apparatus can give a curve showing a relation between X-ray intensity and α-ray intensity which is very approximately linear through

O. W. Richardson and F. S. Robertson. emission of soft X-rays by different elements. photoelectric activity of soft X-rays generated by electron impact on 14 different elements is measured. The soft X-ray yield under given conditions of electron excitation is a periodic function of the atomic member

of the anticathode element.

E. V. Appleton and J. Ratcliffe: On the nature of wireless signal variations (1). Two methods of measuring the angle of incidence of downcoming wireless waves, both involving photographic registration, are described. The first utilises the ordinary night-time signal variations and can be employed in connexion with any steady transmitting station. It only yields useful results if the natural signal variations are small. The second requires a controlled wave-length change at the transmitter, but may be used even when the natural signal variations are large. The mean values of the angle of incidence for the periods immediately following sunset and preceding sunrise show a close agreement, and lead to an effective height of 90-100 km. for the atmospheric deflecting layer. There is a diurnal variation in the height of the ionised layer: it is higher in the middle of the night than during the sunset and sunrise Comparatively rapid fluctuations have been observed in the angle of incidence of downcoming waves. Such fluctuations are considered as being due to 'reflection' at different points on a layer the mean height of which is sensibly constant.

E. V. Appleton and J Ratcliffe: On the nature of wireless signal variations (2). Experiments carried out on the nature of the variations of downcoming wireless waves responsible for nocturnal signal variations. A receiving assembly which is a combination of a loop and vertical aerial eliminates the effects of the ground waves at the receiving station. Large variations in intensity of downcoming waves are found. For wave-lengths of about 400 m. and distances of about 80 miles, fading is chiefly due to changes in the intensity of the downcoming waves. Variations in the phase relation between ground and sky waves are a secondary cause of fading. Changes m the angle of incidence or polarisation of the down-

coming wave are not responsible in any very marked degree for signal variations The downcoming rav has electric vectors both in, and at right angles to, the plane of propagation; similar intensity variations are found in both these vectors.

L H. Martin: The efficiency of K-series emission by K-ionised atoms. The K-series fluorescent radiations have been excited in plates of iron, nickel, copper, and zinc by beams of exciting X-rays ( $\lambda = 0.6$  $\stackrel{.}{A}\stackrel{.}{U}. \rightarrow K$  limits), and the efficiency of K emission determined by an ionisation method. The efficiency of K emission is also deduced for selenium, broinine, and rodine, from some early measurements by Barkla The following values have been found for the K-series quantum transformation coefficient, i.e. the number of quanta of K-series radiation emitted per K-ionised atom Fe (26) 0·29, Ni (28) 0·34, Cu (29) 0 40, Zn (30) 0 46, Se (34) 0 68, Br (35) 0 68, I (53) 0 88 The low values for this coefficient are explained in the hypothesis that in some conditions. as yet undetermined, the excited K radiation does not escape from the atom, but is 'internally absorbed' in the outer electron shells, giving rise to high-speed photo-electrons. It is found experimentally that the probability of K-series emission as opposed to its internal absorption is independent of the frequency of the exciting radiation. The K-quantum transformation coefficient is a function of atomic number, and such that it seems probable that sumlar laws, relating probability of absorption to atomic number and wave-length, hold in cases of 'normal' and internal 'absorption.

Geological Society, May 25.-F S. Wallis: The Old Red Sandstone of the Bristol district. Although the total thickness of these deposits is now estimated at 3000 feet, the faunal contents give evidence of the presence of bods of Upper Old Red Sandstone age only, and no apparent unconformity in the strata or mineralogical break has been detected. Every gradation of deposit between the following types can be found: Coarse- and time-grained samples, cornglomeratic sandstones, siltstones, quartzites, cornglomerates. True found: Coarse- and fine-gramed sandstones, constones, pure limestones, and conglomerates. marks and shales are absent. The material was derived from a pre-Cambrian massif consisting of gneisses, mica- and quartz-schists with abundant quartz augen and volcanic or intrusive rocks, together with a sedimentary series of arenaceous and calcareous (largely silicified) types. This source was situated north-west of Bristol, and its rocks were similar to those of the Mona Complex, and especially to the Gwna Beds of that formation It is not, however, necessary to postulate that the material came from the Anglesey of the present day. The sediments were transported by a great river, which, flowing through a country affected by heavy seasonal or spasmodic rainfalls, finally reached the sea by a broad delta m the neighbourhood of the Bristol district. Lagoons also formed important physiographical features near the coast

#### SHEFFIELD.

Society of Glass Technology, May 18.-G W. Morey and N. L. Bowen: The decomposition of glass by water at high temperatures and pressures. glasses were heated with water in steel bombs for about 20 hours. The bomb was then cooled and the product examined. For optical glasses the amount of attack was greatest with a light barrum crown, and least with the very dense barium crowns, which were remarkably resistant. Of commercial glasses, Jona combustion tubing withstood the action of water best, whilst the failure of Pyrex glass was outstanding.

At lower temperatures Pyrex glass was exceedingly good, but at the higher temperatures of the experiments the boric oxide was completely extracted. The crystals obtained with Pyrex glass at 325° C. were unknown.—G. Gehlhoff and M. Thomas: The brittleness of opal glass. A dense opal glass containing much fluorine was used, the opacity being increased by the addition of zinc oxide. At a temperature of about 1040° C. discontinuous changes take place At high temperatures the glass is clear; in cooling down, crystals of a uniform and small size of grain are precipitated. The glass kept below the devitrification temperature already contains (owing to its having stood longer) bigger crystals. On further cooling down, in conformity with the law of the yet undefined constitution diagram, small crystals are precipitated, whereas the existing big ones still grew. Thus opal glasses must necessarily be worked above the temperature where precipitation of crystals causes opacity brittleness results if they are worked below that temperature.—Francis Redfern, jun. British 15-arm automatic suction bottle machine There are approximately 40 tons of moving parts mounted on the stationary element and the whole machine weighs about 60 tons It will revolve up to speeds of between 6 and 7 revolutions a minute, and is electrically controlled. A week's production of merchantable reputed quart bottles is estimated at 2800 gross. The machine can be produced in three sizes, 6 units, 10 units, and 15 units.

#### PARIS.

Academy of Sciences, May 23 .- A. Lacroix: The meteoric iron of the oasis of Tamentit in the Tociat. This meteorite has been removed to Paris. Its date of fall was about 1400, and it is of interest as being the oldest meteoric iron known. It is poor in nickel and belongs structurally to the ataxite group.—L. Lecornu: The equipartition of energy —C Sauvageau The gametophyte of Nercia filiformis —Charles Nicolle and Charles Anderson The comparative study of some recurrent virus, pathogenic to man.—Gaston Julia A class of polynomials—G. Cerf: A property of invariance of the group of contact transformations and the transformations of certain partial differential equations of the second order with n independent variables.—Corps A new explanation of the negative result of the Michelson-Morley experiment .-W. Arkadiew: Sounds due to the magnetisation of iron.—C. Gutton and Mme. J. Mihul The permeability of iron at high frequencies. The experiments described lead to conclusions in agreement with those of Laville. For wave-lengths varying between 8 and 25 metres, no variations in the permeability of iron could be proved analogous to the variations of the dielectric constant in the neighbourhood of absorption bands.—P. Bovis: Absorption spectra and pleochroism of iodine and of herepathite. Solid iodine possesses a large absorption band with maximum density at wave-length  $0.255\,\mu$ —E. Darmois: The rotatory power of the tartaric ion. A study of the effects of the presence of neutral salts in the tartrate solutions on the rotatory power. In these solutions sodium tartrate undergoes varied modifications in rotatory power both the magnitude and sign of  $[\alpha]$ are changed If it is assumed that these modifications are of a physical nature, it would appear to be very improbable that a single explanation can cover all the cases.—R. de Mallemann: The calculation of the rotatory power of a system of molecules or anisotropic atoms Application to quartz.—Mlle. C. Chamié: The grouping of atoms of radioactive elements in mercury. In mercury the radioactive sub-

stances examined (radium, thorium, actinium, polenium) do not appear to dissociate into individual atoms, but are distributed into small groups of atoms, which show by their photographic effect the a-particles they emit —P Maurice Vèzes The calculation of ionic equilibria —Mlle. Germaine Cauquil Viscosity and geometrical isomerism Derivatives of cyclopentanol and cyclohexanol have been examined from the point of view of the viscosity of the cis and trans isomers and the latter have been found to possess higher viscosities than the former Similar differences would appear to exist in the cis and trans dichlorethylenes but the increase is not so marked. J. Cournot and E. Perot Some special cementations of aluminium and of duralmin after a double electrolytic Researches made from the point of view of the protection of aluminium and light alloys from the corrosive action of sea water -Mme. Ramart-Lucas and M Fasal: Contribution to the study of The 5-methyl-3.3-dialkylpyrrolithe pyrrolidones dones, treated with sodium amide and alkyl halide, react in the lactam form and give N-alkyl derivatives—J Bougault: An example of other-oxide of a ketone hydrate Benzalphenylethylsuccinic and benzylphenylethylmaleic acids.—R. Cornubert Study of the action of sodium amide on cyclohexanone.-F. Blondel. The geological nature of the south-east of Indo-China—E. Bruet The discovery of the upper Pliocene in the valley of Aujon.—Jean Piveteau: Some fossil fishes from the north of Madagascar. One of the specimens collected by Waterlot in the Ambibole region belongs to the genus Acentrophorus, previously only found in the upper Permian in England. A discussion of the Madagascar form shows it to approach the species A. varians and A. glaphyrus — Em. Perrot and Raymond-Hamet: The Yagé, a plant used as a stimulant by the Indians of the Amazon region of the equator and of Colombia. The plant appears to be Banisteria Caapı, and the active principle is an alkaloid, telepathine The poisonous dose for animals (pigeon, guinea-pig, dog) is 200 mgm. per kilogram, and its local anaethetic action resembles that of cocame.—Louis Léger. The nature and evolution of the 'spherules' described in Ichthyophonus, a parasite of the trout. - Huguenard and A. Magnan An accelerograph permitting the direct measurement of the accelerations of a bird in flight. -M. and Mme A. Chauchard: Quantitative researches on the excitability of the apparatus of taste in man.—Jean Roche and Mme. Eugénic Siegler-Soru: The respiration in vitro of the blood of various homeotherm animals—Mile. M. L. Verrier. The transitory cephalic organs of the fry of Acara tetramerus—Jules Barrois: The medusoid stage of Velleles.
—Stelys: The physiological origin of cancer. The
geophysics of a pathogenic medium. Outline of a universal causality.

### GENEVA.

Society of Physics and Natural History, April 21.—L. Duparc: The tectonic of the Tonkin coal basin. The strata of this basin, hitherto generally attributed to the Devonian, are Permo-Triassic. From this follow important modifications of the tectonic interpretations of this basin, the coal of which, sometimes in very thick seams, is of Triassic age.—W. H. Schopfer: The refractive index of the cysticeric fluid and its variations. This index is 1.3358 for the internal fluid and 1.3430 for the external fluid. This index gives interesting indications on the approximate content of the fluid in proteins.—G. Tiercy: The effective temperatures of the giant stars. Applying the formula of Saha corrected for the constant, the

author obtains for the stars of the spectral type M<sub>0</sub>,

 $K_5$ ,  $G_5$ ,  $F_5$ ,  $A_5$ ,  $B_5$ : Giant stars:  $M_0$  2200°,  $K_5$  2900°,  $G_5$  3800°,  $F_5$  5600°,

 $A_5 9200^{\circ}$ . Dwarf stars: M 4000°,  $K_5 4300^{\circ}$ ,  $G_5 6500^{\circ}$ ,  $F_5 8500^{\circ}$ ,

# Science in Non-Self-Governing Dependencies.

OVERNORS and other official representatives of the non-self-governing dependencies of the Crown, recently gathered together at the Colonial Office Conference, devoted no little attention to a consideration of the function of scientific research in the development of the territories for which they are responsible, and the means by which this research is to be promoted. The outcome of their deliberations is the report on Colonial Scientific and Research Services which they approved and adopted on May 27, and is now available to the public in the published proceedings of the conference—the first of its kind.

From the point of view of research, no more favourable time could have been chosen for this first conference. It has followed closely upon the visit of the Parliamentary Commission to East Africa in the latter part of 1924, the personal visit of the Under-Secretary of State for the Colonies to West Africa in 1926, the tour of Mr. Roy Wilson and Mr. Harry Snell to British Guiana this year, and the reports which were presented to Parliament at their conclusion, in all of which the dependence of economic development upon the creation of new knowledge and the application of existing scientific and technical knowledge was emphasised. Furthermore, it is only a few months since the Premiers and other representatives of the self-governing Dominions met, and were led to consider similar problems and approved a report of a sub-committee which they appointed on Empire research.

The changed attitude of the Dominion premiers towards scientific research as manifested in that report was the subject of comment in these columns at the time. At the Imperial Conference in 1923 they sought for a solution of their economic problems in political expedients; three years later they decided to give science a trial. Upon this result the present political heads of the Colonial Office can be congratulated, for they have assiduously preached the gospel of science for the past two years.

Under influence of the same stimulus, the representatives of the non-self-governing dependencies have reacted in the same way as the Dominion representatives. One of their first acts in conference was to appoint a committee under the chairmanship of Lord Lovat "to frame and submit a scheme, based on contributions to a common pool, for the creation of a Colonial Scientific and Research Service available for the requirements of the whole

Colonial Empire, for the support of institutions required for that purpose, and for the increase of research and study facilities in connexion with the specialist services of the Colonics generally."

In the general statement of the problem the Committee has drawn largely upon the information contained in the report of the Committee on Agricultural Research and Administration in the Non-Self-Governing Dependencies, of which Lord Lovat was also chairman. Its recommendations are almost identical with those put forward in that report, and follow the general principles enunciated in the report of the East Africa Parliamentary Commission for the effective prosecution and coordination of research. The modesty of its proposals, however, will be gauged from the fact that the scheme proposed for the reorganisation of the colonial agricultural services involves an annual expenditure of £175,000 in all, a considerable proportion of which is at present a charge on colonial revenues. This is a very small sum when regarded from the point of view of the needs of colonies covering a total area of roughly 2,000,000 square miles, the populations of which-mainly agricultural—number 50,000,000, controlled by thirty distinct administrations. It is illuminating to relate the cost of such a service to the exports from the colonies to the United Kingdom. These exports, mainly agricultural, have quadrupled in the last twenty years and amounted to £81,000,000 in 1925. In that year "they were greater than those from the whole of India, or from any single one of the self-governing Dominions." If the total agricultural exports of the colonials are taken into account, including rubber, the cost of the proposed service works out to 1 of a penny in the pound. The Committee states that so far "the aid of science has been but half-heartedly invoked," but it is difficult to see how this state of affairs is to be remedied with such meagre financial provision.

The committee is well aware of the needs of research. It appreciates the fact that "there is severe and growing competition between the sources of raw materials and food-stuffs for the supply of the world's markets"; that "the ravages of diseases, particularly among the luxuriant conditions of tropical life, are ever increasing"; and that "science, and science alone, can enable us to increase production by improved methods, and, at the same time, combat successfully the diseases which these new methods bring in their train." It notes that the "United States, the area of which is one-third larger, and the population a little more than double that of our

Colonial Empire, spends more than £4,000,0000 annually on agricultural research"; and that Egypt spends nearly twice as much annually on agricultural entomology as the whole of the British colonial governments, most of which are faced with far graver problems than Egypt. Unfortunately, the committee gives no indication of the expenditure of France, Belgium, or Holland on agricultural research in their respective colonies; but we know that the Dutch maintain Buitenzorg splendidly while the Amani Institute is still lying derelict, untenanted, unstaffed; we know that the French are devoting much attention to the investigation of nagana (tsetse-fly disease in cattle), and are attempting to breed immune types, while we continue to starve the veterinary research stations in East Africa, and to expect the research staffs to devote a considerable proportion of their time to the preparation of sera for inoculating cattle against the various diseases which decimate the natives' herds.

In view of the condition of affairs regarding research and research institutions and the scientific services generally, as disclosed in the various reports to which we have referred above, in fact, to the complacent indifference to science which characterises our colonial administration, and the statement of Lord Lovat's Committee that "there is no organisation whatsoever in the colonies which views the problems of science as a whole," we can but admire the forbearance of the committee in stating that it is anxious not to give the impression that it is trying to be dietatorial to the colonial governments. It is well, however, that it has obtained general consent to the establishment of a central fund maintained by contributions from the various colonies. This should ensure continuity of research, and safeguard the individual scientific officer against the excessive zeal of colonial governments to reduce their scientific staffs in times of financial stringency. The evident purpose of the committee's recommendations is to make the research services of the colonies attractive to the best type of worker, and this is certainly a greatstep forward.

The committee felt itself unequal to the task, in the short time available, of formulating proposals for the creation of a unified research service, postulating as it does modifications in the organisations (existing and proposed), the creation of links between various sciences not only in the colonies but also through research organisations at home and in the Dominions That task is left for another committee, which will have the advantage of making

fronting them.

The Lovat Committee, however, is quite definite as regards the organisation of a colonial agricultural research service. It recommends that a central council should be constituted with a chairman (who should be a layman), a director (who should be a recognised man of science), and a deputydirector (who should have had administrative experience in the tropics). The formal channel of communication between the council and the Secretary of State should be through the chairman. The members of the Council should be the directors of the Royal Botanic Gardens at Kew, of the Imperial Bureau of Entomology, and of the Imperial Bureau of Mycology, a chemist, and representatives of veterinary science, of the Imperiaf Institute, of the Colonial Office, and of the Empire Marketing Board. Liaison with the Medical Research Committee and any other research committee should be maintained either by co-opting a member of that committee as occasion required, or by creating an ad hoc committee of members of the bodies concerned to deal with borderline questions.

The proposed constitution of the council is open to criticism. No reasons are given for the choice of chairman. What precisely is meant by a layman? Is he to be a man whose impartiality and sound judgment are to be guaranteed by his complete ignorance of science ? Exception might be taken also to the selection of the scientific representatives. Presumably botany, mycology, entomology, and chemistry are regarded by the committee as the four sciences of most importance to agriculture. Two of them are mainly concerned with the pathological aspects of agricultural research, admittedly of importance, but certainly not so important as research in genetics aiming at the production of new varieties of plant and animal types resistant to disease. At least one geneticist should be added to the council. The claims of physicists to representation on the council are also strong. A physicist would be able to advise on most problems in connexion with the relationship of soil and climate to plant life as well as those concerned with the transport and storage of agricultural produce. If there is a fear that the council would be too unwieldy, the substitution of an agriculturist—say the director of Rothamsted Experimental Station—for the four scientific members proposed by the committee, would preserve its balance and not diminish its effectiveness as a council. Perhaps it is not too late, also, to suggest that an ex-member of the Indian agricultural services should be given a seat on the Many of the difficulties which beset agriculturists in the colonies are identical with those which have already been successfully surmounted in India by the application of research, and it would be well for the council to have the advice of some one thoroughly familiar with the methods already successfully adopted there. A further point might also be considered. The principle of automatic retirement of members of advisory councils after a short term of years has already been applied to membership of the Medical Research Council and the Advisory Council for Scientific and Industrial Research. If the Colonial Agricultural Research Council is constituted as proposed, this principle could not be applied.

The observations of the committee on the need for attracting the best talent to the colonial agricultural services will commend themselves to scientific workers as a whole. It must provide a career. "It must be well paid, and the financial prospects held out must be better than those which obtain at present." An officer entering the unified service must be liable to transfer, but he must be safeguarded against any loss on transfer recommended that retiring benefits for the members of this service should be provided by a provident fund scheme Transfers of research officers to the administrative side of agriculture would not then present any difficulties in this regard. Before the recommendations of the conference can be translated into facts, however, the committee which has just been appointed by the Secretary of State for the Colonies has to go fully into the question of finance and submit its proposals to the colonial governments. This procedure involves vexatious delay and might have been obviated

The tentative proposals of the committee on the unification of the various colonial research services need not be considered at this juncture. It will be time enough to deal with the matter when it is made the subject of a report by the further committee which is to be set up. The progress made in connexion with the agricultural research services will be studied with interest, and once the recommendation of the conference is made operative, that the poorer colonies will be entitled to command the services of first-class men from the central pool—equally with those, colonies with greater financial resources—provided their problems are of sufficient importance, no excuse will remain for their starving these essential services.

## The Gentle Art of Chemical Controversy.

Essays on the Art and Principles of Chemistry: including the First Messel Memorial Lecture. By Prof. Henry E. Armstrong. Pp. xxxi+276 (London: Ernest Benn, Ltd., 1927.) 15s. net.

WHILE we regard parts of this book as beneath the dignity of the science the art and the principles of which it professes to expound, we cannot repress some feeling of sympathy with the author for the courage he shows in resisting superior forces. We can admire Prof Armstrong's defence of the name of 'oxygen,' we can appreciate his insistence that water acts chemically when dissolving salts. but is anything gained by crude lampoons on van't Hoff, Arrhenius, and Ostwald—and indeed on the whole school of modern physical chemistry founded on their work <sup>2</sup>

The motif of the book appears to be that chemists are not only a perverse and unthinking crowd, easily hypnotised by any 'Nordie' magician who can work the spell of the integral calculus, but also, having been inoculated with the ionic virus, are unable to see the clear facts which Prof. Armstrong has been putting before their eyes for the last forty years. Why should this be? Probably the force of prejudice and of dictated belief has blinded them: they have not understood. The case must be presented again in a more comprehensive and definite way.

The root of the trouble is twofold: people have never grasped that water is not the simple, neutral, self-satisfied body made up of an oxygen atom holding a hydrogen atom in each of its two hands—it is a far more complicated affair, a mixture of 'polyhydrones' of various orders of complexity holding in solution simple 'hydrones' (H<sub>2</sub>O), the capture of which by molecules of dissolved salt or acid alters the physical properties of the solvent; and, secondly, no chemical action can take place unless there is a tertium quid—usually conducting water—to form an electrolytic system through which the change occurs.

The year 1885 must still be sodden with the tears of things. In that year Prof. Armstrong first preached the true doctrine to the Chemical Section of the British Association; in that year the conception of the dissociation of salts in dilute solution became known—to use Prof. Armstrong's phrase, "Arrhenius came forward as a Whole-Hogger"; and "in 1885 van't Hoff, assuming the character of the Hatter, invited us to a scientific Mad Tea Party, at which he out-hatted the Hatter." But even this combination of 'genius' and 'youthful

enthusiasm' would not have prevailed alone to spread the 'joke'; it was carried far and wide by "floods of Ostwaldian ink." Is not this language a little reminiscent of a celebrated criticism of the Hallucinations and the 'Phantasiespiclereien' of a certain Dr. J. H. van't Hoff, and does not our modern Censor rather out-Kolbe Kolbe?

Chemists can understand the protest against the idea that water, acting as a solvent, is a mere material vacuum-chamber affording room for the salt to dissociate; they can believe it is an active chemical substance, and that the action between salt and water is reciprocal. Here is a strong position to hold, but Prof. Armstrong is not content to hold it. The salt, or the acid, cannot react with water without an intervening electrolyte. "Take," he says, "pure non-conducting water and pure non-conducting hydrogen chloride: they cannot react chemically, but they can form a couple by some mechanical 'attraction' or process of 'dis-This couple (being an electrolyte?) tribution.' can now bring about union between it and another pair of molecules to form a complex which splits up into two bodies—one, 'muriated hydrol,' the other, 'hydrone chloride.'" We are given a picture of the process, which we partly reproduce:

So far the conception seems clear, but afterwards it is harder to follow. The two hydrogen chloride molecules have each incorporated a volatile hydrone molecule, and by so doing have altered the physical properties of the solvent; but one has to account for each molecule of hydrogen chloride producing double the effect of a neutral non-conducting molecule. It seemed at first sight that Prof. Armstrong considered the 'hydrone chloride' molecule to be more readily acted on by hydrone than its sister hydrol, and we pictured a further process taking place:

$$H_{2}O + OH = H_{2}O + HCI$$

$$H_{2}O + OH = H_{2}O + HCI$$

$$H_{2}O + OH = H_{2}O + HCI$$

$$H_{2}O + HCI$$

$$H_{3}OH = H_{2}O + HCI$$

The hydrogen chloride liberated in the last equation would presumably repeat the cycle, so that finally for every HCl molecule dissolved, one hydrone would be captured and held bound as 'muriated hydrol,' while two hydrones would be incorporated as hydronol which is represented as a stable molecule. That this is the interpretation meant by Prof. Armstrong seemed confirmed by his statement (p. 266) that the osmotic activity is to be attributed, in a dilute solution of hydrogen chloride, to the molecules of muriated hydrol and of hydronol. It will be noticed that in this interpretation every HCl molecule dissolved affects three, and not two, hydronic molecules. but in the equation suggested on page 264 to account for the production of hydronol both the hydrone chloride and the muriated hydrol react with hydrone and all the hydrogen chloride is liberated:

If the two HCl molecules liberated in this equation are free they would, presumably, repeat the original cycle until *all* the free hydrone was converted into 'hydronol' But if they form the

H complex ClH (labelled d on p. 263) and this is

unacted on by hydrone, then each HCl molecule has only anchored one hydrone.

Probably Prof. Armstrong can devise some way out of the difficulty which eludes us, or possibly we have been caught by a snag somewhere. When a man prides himself on his clear and forcible English, what are we to make of the following statements? On page 266 he writes: "This osmotic activity is to be attributed. . in a dilute solution of hydrogen chloride, for example, to the molecules of muriated hydrol and of hydronol,

he says. "As the concentration is lowered, under

the influence of hydrone, the complex RX OH

is more and more converted into hydronol. Ultimately the solution contains the solute only in the

 $\operatorname{form} H_2O$  together with an equal number

of molecules of hydronol." The difficulties of No. 3010, Vol. 120]

following the hypothesis of electrolytic dissociation seem small in comparison.

Similarly in all cases of oxidation, whether it be a solid or a gaseous fuel that is burnt, hydrone is the sine qua non. Take that peculiar gas carbonic oxide. "It is commonly recognised," Prof. Armstrong writes, "that this gas cannot be burnt dry, but that the rate of combustion rises as the amount of hydrone in admixture with it is increased, up to a certain point; hydrone apparently plays a peculiarly active part in its combustion, primarily through incorporation into its being In fact, it is difficult to think of hydrone as active in conjunction with carbonic oxide except by giving rise to formic acid, the two molecules cannot well grip each other at all with any other result." That carbonic oxide can directly grip with hydrone to form formic acid seems to be an advance on the doctrine that no chemical action can take place between two molecules unless there is a third and conducting body to act as go-between, but obviously in this instance, as with hydrogen chloride, the hydrone plays a double part. It can 'grip' or 'disperse itself over' carbonic oxide, and then "given the initial production of formic acid, all else in the behaviour of carbonic oxide is clear."

Prof. Armstrong complains that his work has not been appreciated, his explanations not heeded. "Since 1885," he writes, "my voice has been that of one crying in the wilderness." But the voice of one crying in the wilderness—as prophesied by Isaiah—surely was listened to Are we not told that not only Jerusalem went out to hear, but "all Judæa, and all the region round about Jordan"? The voice has been heard, but is not the answer more nearly that pagan rejoinder, "Credat Judaeus"?

# Scientific Research and the Veterinary Profession.

The Physiology of Reproduction in the Cow. By John Hammond. Pp. xvi + 226 + 33 plates. (Cambridge. At the University Press, 1927.) 21s. net.

IN the modest preface to this book, the author expresses his hope that it will be of use to those who engage in research on the subject he deals with, and at the same time form a reference book for advanced students in agriculture and veterinary science. We have confidence that his hopes will be fulfilled.

Those who have learnt to value the care and

accuracy which characterise all Mr. Hammond's work will find in this book increased reason for appreciation of those qualities in the author. It is not only a masterly exposition of the physiology of reproduction in the cow; it also deals in a truly scientific spirit with gynæcological problems of the first importance to members of the veterinary profession, and therefore to their clients, the practical breeders

The volume is divided into (1) a short account of the breeding season; (2) the cestrous cycle, which occupies the bulk of the book; (3) pregnancy; and (4) sterility. The method of investigation the author adopts will be best disclosed by a brief survey of the section on the cestrous cycle.

Mr. Hammond examines the periodicity and rhythm of the œstrous cycle in relation to the time of year, the age, the state of fatness, the effect of drugs, the psychological effect of proximity of the bull, the effect of service of the bull, and the result of artificial removal of the corpus luteum; and wherever possible supports the conclusions he arrives at with elaborate tables of figures. The duration of cestrus he treats in a similar elaborate manner, and comes to the conclusion, which we think is justified by his records, that the length of the cycle and the duration of œstrus are correlated phenomena. But the main portion of this section is devoted to a detailed account of the physiological, anatomical, and histological changes which take place throughout the whole of the organs concerned with reproduction during the œstrous cycle, and with the mammary gland; a most painstaking and valuable piece of work.

It is impossible to do justice, in a critical sense, in the space at our disposal, to what may be described as a monograph of more than eighty pages containing fourteen elaborate tables and illustrated by a prodigal number of drawings and photographs contained in nineteen admirably executed plates. Much of it, of course, consists of a critical examination of work done by others. and when we add that the author's bibliography contains references to four hundred books and papers, some idea may be gained of the labour involved in the work. A welcome feature of this portion of the author's duties is his generous appreciation of the work of others and his judicial tolerance in criticism. We would assure him that the weight of his judgment is not decreased thereby.

Mr. Hammond's account of the anatomical and histological changes which take place in the ovaries during the cestrous cycle are specially worthy of

note, more particularly, perhaps, in relation to the Graafian follicle and to the corpus luteum. Much of this is new, and in some ways highly suggestive, while the tables and figures he gives are illuminating. With some of his general conclusions we are in entire accord, as, for example, in his refusal to accept the theory that the ripening of the Graafian follicle is the direct cause of menstruation. On the other hand, we have failed to convince ourselves of the truth of the view that the duration of the corpus luteum solely controls the length of the estrous cycle, a view which he finds reason to accept

If we must particularise, however, it is Mr. Hammond's original work on the mammary gland, on its growth, the histology of its development during feetal life, and from birth to the age of puberty, and the relation of different forms of development to the production of milk, which strikes us as fraught with matter of special scientific importance and economic value.

The section concerned with pregnancy contains a valuable résumé of the work of a host of observers on a variety of domesticated animals; it is, in fact, a comparative study of more considerable interest to the scientific worker than to the practical breeder, though of undoubted value to the veterinary student. Here and there, however, these observations have practical significance, as for example the correlation between the time when the proportion of feetus exceeds that of the feetal fluids, and the liability to infection with *Bacillus abortus*.

The changes which take place in the uterine tissues during pregnancy are very fully described and of much interest; especially in regard to the destructive action of the feetal membranes on the cotyledons, and the attachment of the foctal placenta thereto by finger-like growths which eat their way into the tissues of the cotyledons, where they are interlocked by growths of the maternal connective tissue and do not project freely into blood lacunæ. The occurrence of pustules on the internal surface of the amnion and their relation to the amount of mucus in the amniotic fluid is recorded, but beyond the fact that they are said to contain large quantities of glycogen and that they are temporary structures, nothing seems to be known of their metabolic function. It occurs to us that the association of their breakdown and the simultaneous cessation of the secretion of feetal fluids with the glandular phase of growth of the udder, are correlated phenomena which it might be worth while to investigate. In this section also

the work done on the histological changes which take place in the udder, and the nature of its secretions at different stages of pregnancy, is of marked value.

It is to be hoped that the brief concluding chapter on sterility may be extended when a call is made for the next edition of the book. There is no subject associated with the breeding industry, especially the breeding of thoroughbred stock, of greater importance than this, and there is no subject of which both the man of science and the veterinary profession are more profoundly ignorant.

## Scientific Studies in a Swiss Nature

(1) Der schwerzerische National-Park. 50 kunstlerische Aufnahmen von J. Feuerstein. Pp. 1v + 48 Tafeln. (Zurich: Brunner und Co. A.-G., n d.) n p

Reserve.

(2) Vegetationsentwicklung und Bodenbildung in der alpinen Stufe der Zentralalpen. Von J. Braun-Blanquet unter Mitwirkung von Hans Jenny. (Mém. de la Soc. Helvétique des Sci. Nat. Vol. 63, Mém 2, 1926) Pp. viii+181-349. (Geneva, 1926)

ROBABLY few whose pursuits have not brought them into wide as well as intimate contact with Nature, can realise the extent to which the face of the globe has been modified by the restless activities of the human race. The modifying influence of man is more particularly experienced by the organic film which tends to cover, now thickly, now thinly, those portions of the surface of the earth which are capable of supporting life. Nowhere, perhaps, is this influence more noticeable than in the case of vegetation. For this reason plant ecologists have up to the present tended where possible to select for study the more 'natural' types of vegetation, i.e. those least altered by man and his domestic animals. It is gradually coming to be realised, however, that many of the problems of agriculture, dealing as it does with 'semi-natural' vegetation such as pastures, as well as with vegetation in its most 'artificial' aspect, the crops of arable land, are really ecological problems.

Though, however, no doubt ecology in the future will occupy a not unimportant position amongst the applied sciences, in this, as in other cases, pure science is fundamental. Such experiments, therefore, as that now in progress on a large scale in the Swiss National Park, are being watched by ecologists with considerable interest. The

- Swiss "Commission for Nature Protection" is to be congratulated on its decision to allow natural processes to operate in this area of upwards of fifty square miles, entirely free from the disturbing influence of man. Here man is content to stand aside, and merely to observe and record. The two works reviewed below deal with this great Nature reserve, but from very different points of view.
- (1) The first is merely a 'Nationalparkalbum' of some fifty photographs by J. Feuerstein, with forewords by Prof. Schroter and H. Federer. Yet the album is worthy of its subject, for Herr Feuerstein is at once a skilled photographer and an enthusiast thoroughly familiar with the Park and its inhabitants. Artistically and technically the photographs reach a high standard; they are well reproduced, and most of them are of whole plate size. The photographs themselves possess considerable scientific interest. The landscapes give a good idea of the ecological character of the district, especially of the coniferous forests on the mountain slopes and the alpine zone above. There are some excellent photographs of a few wellknown plants such as Ranunculus alpestris and Crocus albiflorus, and of a number of animals. The latter include the marmot, chamois, roe deer, ibex, foxes, and the kite and other birds. One particularly attractive photograph shows an alpine hare seated on the snow.
- (2) The second of the two works under consideration is an important contribution towards the scientific exploration of the Swiss National Park, dealing with the development of both soil and vegetation above the tree limit. The vegetation in question is well seen in several photographs in the 'Album.' Dr. Braun-Blanquet is responsible for the vegetational portion of the memoir, and Dr. Jenny, of the Agricultural-Chemical Laboratory, Zurich, for that devoted to soils. The work has gained greatly by this co-operation.

The underlying thesis, well established by convincing evidence, is that soil and vegetation undergo a parallel genetic development. Both exhibit initial an l transitional stages, and both tend towards a more or less stable ultimate condition, the soil climax and the vegetation climax respectively. Soil development is primarily conditioned by climatic factors, especially temperature, precipitation, and evaporation. The combined action of these factors ultimately produces a definite soil type which occurs, under similar climatic conditions, on every geological or petrographical substratum where soil formation

1 See article by Prof. C. Schröfer, NATURE, Sept. 29, 1923; vol. 112, p. 478.

has progressed to the final stage. The soil type then is a function of climate, and it should be possible therefore to speak of a 'climatic climax' in the case of soils, as we already do in the case of vegetation In the humid climate of the alpine zone in the Central Alps the progression, owing to leaching and the accumulation of humus, is invariably from basic or weakly acid soils towards a strongly acid climax—the alpine humus soil. This order of development is irreversible. So far as plant succession is concerned, the gradual changes in soil reaction are accompanied by a struggle between the pioneer species characteristic of basic or less acid soils, and invaders capable of flourishing in increasingly acid soils. The climax community, on the strongly acid alpine humus soil, is dominated by Carex curvula. There is thus a very close parallel between soil succession and plant succession. The authors regard the progressive changes occurring in the soil as the immediate cause of plant succession, the climate mainly affecting this succession indirectly through the soil.

40

Another point of general interest is the apparently great importance of wind-borne dust. This dust aids in the building of soils; compensates to some extent for the leaching out of soluble salts -thereby, in the case under consideration, retarding plant succession; is a source of mineral nutriment for plants-indeed the chief source, according to the authors, in the case of shallowrooted plants growing in acid humus soil: and finally, serves to infect the soil with spores and seeds. The authors quote the opinion of Treitz, expressed at the International Soil Conference at Prague (1924), to the effect that "the most important soil-forming and plant-forming climatic factor is the annually deposited amount of windborne dust." At first frankly sceptical regarding this somewhat sweeping generalisation, the authors investigated the matter for themselves, by collecting and therefore immobilising blown dust in 'rain totalisators,' placed at two elevations in the Val Cluoza. The results obtained were truly remarkable. At the upper station, for example, above the tree limit at an altitude of 2340 m., the dust was collected continuously for two years. The average deposition over this period worked out at about 6.46 tons of dust per acre per annum, of which - about 1-63 tons were CaCO<sub>3</sub>. Such heavy manuring by wind action alone seems almost incredible, but if true would justify the authors' opinion that alpine vegetation depends for its supply of mineral salts to a great extent on wind-borne dust. Similar

experiments would be well worth carrying out in Great Britain. Hitherto, with the obvious exception of accumulations of wind-blown sand, little or no attention has been paid by ecologists to what seems likely to prove an important factor of the plant environment.

The memoir contains a mass of careful detailed work which cannot be dealt with here, beyond saying that Dr. Braun-Blanquet has described and analysed a large number of plant associations forming the complex of communities leading to that dominated by Carex curvula. He has, moreover, attempted to group these associations into alliances, according to their floristic relationships. On the whole, the monograph is certainly one of the best that has so far emanated from the Zürich school.

R. H. Y

## Psychopathology.

An Outline of Abnormal Psychology. By Prof. William McDougall. Pp. xvi + 572. (London: Methuen and Co., Ltd., 1926.) 15s. net.

EDICAL psychology has had a long and varied history. In its earliest stages it dealt with magical and pseudo-religious phenomena, which it took at their face value. Even within the last century it remained mainly anecdotal, with a complacent acceptance of the miraculous and the supernormal. With the earlier investigations and writings of scientists still among us, such as Dr. Pierre Janet and Dr. Morton Prince, it passed into the stage of detailed descriptions of outstanding cases of mental abnormality, especially of hysterical cases with their startling characteristics of dissociation and susceptibility to hypnotism. Only within the last thirty years has it taken on the characteristics of a definite sciencethat of psychopathology—with a systematic classification of its subject matter and a set of general principles genuinely explanatory in nature. In the course of its development it has profited greatly by the advance of normal psychology, but is now reacting strongly upon the latter science, deepening its conceptions and revealing the presence of dynamic factors in the normal mind which would otherwise have remained unobserved and unsuspected.

In Prof. W. McDougall's "Outline of Abnormal Psychology" we have the first serious attempt at a systematic and detailed text-book on the subject. It is a sequel to his already well-known "Outline of Psychology," and is written on the lines of general

psychological theory there set forth. In a series of thirty-four chapters, all the main aspects and problems of the science are fully dealt with. Throughout the volume detailed descriptions of typical cases, to the number of sixty in all, are given, which furnish a solid empirical foundation to the theoretical superstructure. Although full accounts are given of the chief schools of thought in modern psychopathology, such as those of Janet, Morton Prince, Freud, Jung, and Adler, these are successfully pressed into service to illustrate the author's own systematic psychological theory, the vitality of which is shown by its power to assimilate much that is characteristic of each of them. In this respect McDougall is representative of a flourishing school of psychopathology and psychotherapy especially prominent in England at the present time.

Certain minor points may be singled out for qualified criticism. The theory of causation of exaltation and depression (manic-depressive insanity), in terms of the instincts of self-assertion and self-abasement, would seem to be too simple. It does not allow for the large part played by 'disappointment in love,' understood in the widest sense, often found in these cases when deeply investigated. Again, the author unduly minimises the correlation of pronounced hypnotic phenomena with those of hysterical dissociation. This is no doubt not unconnected with his readiness to accept at their face value the manifestations of alternating and multiple personality. its turn, involves him in the necessity of producing an ingenious but singular theory of 'monads' in telepathic relation with one another to explain the forms of internal communication and lack of communication within these split personalities. Such monads are different from their Leibnizian prototypes, since the latter 'had no windows.' Moreover, to bring in telepathy as a thoroughgoing explanatory factor in this way seems perilously near explaining ignotum per ignotius.

We should bear in mind the alternative possibility that the phenomena of multiple personality may be in the main artefacts, due to the hypnotic methods of investigation and treatment employed by their observers. This would fit in with the fact that during the recent European War, in which severe forms of functional nervous derangement were produced by the thousand, no well-marked cases of multiple personality were reported or observed. Cases of extensive amnesia, fugues, etc., were numerous; but the first aim of the army doctors in the battle areas was to remove these

amnesias and re-associate the patients as quickly as possible, so that the latter might be either returned to the line or sent down to the base with the minimum of delay. Moreover, we should not overlook the part played by drama, or rather melodrama, in producing well-marked phenomena of multiple personality.

Finally, Prof. McDougall makes a vigorous onslaught upon the theory of 'abreaction' or psychocatharsis as a working off of pent-up emotion leading to recovery. But in explaining the beneficial results of this method as due to a re-association of the mind, he is only restating the theory of his selected opponent, set out in publications already some years old. The essence of his opponent's theory was that the rearousal of disturbing emotional experiences with sensorial vividness was in certain cases alone adequate to produce a re-association of the mind with the requisite degree of completeness. The reassociation must be an emotional one as well as an intellectual one.

These matters are, however, of subsidiary importance. In its powerful sweep, firm grasp of detail, and vivid and lucid style, the book stands out as one of the most important contributions to psychopathology of the present time.

WILLIAM BROWN.

## Our Bookshelf.

(1) The Food of some British Wild Birds: a Study in Economic Ornithology. By Dr. Walter E. Collinge. Second revised and enlarged edition. Pp. xix + 427 + 9 plates. (York: Published by the Author, Yorkshire Museum, 1927.) n.p.

the Author, Yorkshire Museum, 1927.) n.p.
(2) The Birds of the British Isles. By T. A.
Coward. (The Wayside and Woodland Series.)
Third Series Comprising their Migration and
Habits and Observations on our rarer Visitants.
Pp. xi+308+127 plates. (London and New
York: Frederick Warne and Co., Ltd., 1926.)
10s. 6d. net.

(3) British Birds. Written and Illustrated by Archibald Thorburn. New edition. In 4 vols. Vol. 4. Pp. x + 154 + plates 145-192. (London: Longmans, Green and Co., Ltd., 1926.) 16s. net.

(1) ALTHOUGH Dr. Collinge modestly calls this a revised edition of his work of 1913, it is virtually a new book. In place of the twenty-nine species formerly considered, the feeding habits of seventy are now discussed in detail, a considerable number being sea-birds, which had no place in the earlier work. The data for most of the species have been extended, the volumetric system of analysis, now universally adopted in the United States of America, has been superimposed upon the numerical

system, and the useful chapters dealing with general aspects of the economic relationships of birds have been added to and expanded. On the whole, it is surprising in how many cases an analysis of the food stuffs taken over a long period tells in favour of birds usually condemned as unmitigated pests, even although the statistics here given reckon against the bird much in the food content which can be of no agricultural value. The statistical methods adopted in such investigations still fall far short of scientific precision and leave the final judgment to personal interpretation with wide margins, but until better methods are evolved, Dr. Collinge's book will remain the standard British work on the subject

(2) For the average naturalist this third volume completes the most attractive and useful of the lesser books on British birds. As a practical guide to species it is less essential than its forerunners, since it deals mainly with rare and casual visitors. It is illustrated by many fine coloured drawings reduced from Lord Lilford's standard work. But it breaks new ground by introducing several chapters dealing with general aspects of British bird life, including a lengthy and excellent account of migration, and descriptions, family by family, of characteristic migratory and other habits. The sixteen 'sub species' added to the British list since the earlier volumes appeared are here described, as well as two species since recorded for the first time from Great Britain.

(3) The appeal of Mr Thorburn's work rests largely upon the beautiful and accurate coloured plates, the finest of their kind, which make identification of species a pleasure and a matter of comparative simplicity. Since, except for a number of rare and closely related species, all the British birds appear in these 192 plates, descriptive matter has been reduced to a minimum, and the text is confined to short accounts of range and characteristic habits.

- (1) Civilisation or Civilisations: an Essay in the Spenglerian Philosophy of History. By E. H. Goddard and P. A. Gibbons. Pp. xvi+231. (London: Constable and Co., Ltd., 1926.) 7s. 6d. net.
- (2) Sunrise in the West: a Modern Interpretation of Past and Present. By Adrian Stokes. Pp. xvi+168. (London: Kegan Paul and Co., Ltd., n.d.) 7s. 6d. net.
- (1) In a preface to "Civilisation or Civilisations," Dr. F. C. S. Schiller, with a characteristic and mildly cynical humour, discusses the reasons for teaching history and briefly expounds the philosophy of that subject as an attempt to formulate a 'law.' The book itself is intended to familiarise English readers with the ideas of Spengler's book, "Der Untergang des Abendlandes," in which the belief in progress was challenged. Holding that civilisation does not show any steady arithmetical progression, Spengler propounds a 'law of civilisations' to account for their rise and fall. Human achievements are divided into nine groups or eras, each constituting a distinct civilisation capable of

high achievement in art, in science, in thought, in religion, and in social organisation. Each of these passes through a course of progress covering about 1400 years, after which the society ceases to be artistic, social, or scientific in any but the crudest sense. Western civilisation, beginning about A.D. 900, is expected to come to an end about A.D 2300. It will be seen that this theory of history involves a return to the schematisation of progress, and indeed the authors will have nothing to do with the archæologist who traces cultural phenomena back to their origins or with the diffusionist and his migrations of culture from an original centre in Egypt Either school may perhaps be content to await the verdict of the facts—when we know them.

(2) "Sunrise in the West" is essentially modern in outlook and in language—both to the plain man a little obscure. The culture of the west is reviewed as a progress in the relation to one another of the 'poetry' and 'prose' of human expression. Our present position is a stage before the apotheosis of western civilisation, and the flame of the Western Spirit is a 'blue vision' which the author himself characterises as "an unsatisfactory expression, no doubt"!

The Riddle of the Tsangpo Gorges. By Capt. F. Kingdon Ward. Pp. xv + 328 + 16 plates. (London: Edward Arnold and Co, 1926.) 21s. net.

THE Tsangpo River, the main source of the Brahmaputra, flows placidly, from west to east, across Tibet until it reaches the eastern end of the Himalayan range, and vanishes into a terrific gorge. The bottom of the gorge is 9680 feet above sea-level, and the peaks that hem it in on each side rise to more than 21,000 feet. The river emerges from the mountains some 35 miles away, and is then flowing south and west at an elevation of less than 2000 There was, therefore, a chance that the gorge might conceal the most stupendous waterfall. Part of the gorge was explored by Bailey and Morshead in 1913, and most of the remainder by Captain Kingdon Ward and Lord Cawdor in 1924. No large falls were found, and it is now clear that none exists.

The main purpose, however, of Captain Kingdon Ward's expedition was not the exploration of the gorge, but the collection of plants and seeds. In this corner of Tibet the climate varies from tropical to arctic, and from humid to arid, within a range of a few miles, and the flora varies with the climate. It is a wild garden stocked with countless species and varieties of flowers and flowering shrubs; hillsides blazing with rhododendrons; fields of lilies; meadows of primulas; giant snowpeaks above, and below the abyss, echoing with the thunder of the hidden river.

The book is very modestly written, and the dangers and difficulties that were faced and surmounted in the gorge are mostly left to the reader's imagination. It is probable that they will not be fully realised until some other explorer attempts to follow in the footsteps of Captain Kingdon Ward

and Lord Cawdor The expedition owed much to the hospitality of the Tibetans, and to the courage and endurance of the men and women who, at the risk of life and limb, carried their loads up and down the almost vertical cliffs of the gorge The book is illustrated by excellent photographs, some of which must have been taken from very perilous positions. The last two chapters of the book are by Lord Cawdor, and give a short account of the natives of Eastern Tibet and their customs.

Reports of the Progress of Applied Chemistry, issued by the Society of Chemical Industry Vol 11, 1926. Pp. 742. (London The Society of Chemical Industry, 46 Finsbury Square, E.C 2, 1927.) 12s 6d., 10s. to Fellows of the Chemical Society, or 7s. 6d to members of the Society of Chemical Industry.

ONE is accustomed to anticipate with some eagerness the publication of the annual reports on pure and applied chemistry by the Chemical Society and the Society of Chemical Industry, respectively The eleventh volume (1926) of the latter series will occasion no disappointment In fact, it is unusually comprehensive; it is readable and yet as full as ever of catalogued information, and, moreover, it has appeared promptly. It is not surprising that constant reference is made to the impression left by last year's dispute in the coal-mining industry on the progress of applied chemistry; however, the difficulties of that period have at least focussed attention on fuel economy, on more fruitful ways of using coal, and on the possibility of meeting future demands for liquid fuel.

It is noteworthy that the period under review saw the establishment of the Institution of Fuel Technology and the Fuel Section of the Society of Chemical Industry. The fermentation industries, also, continue to grow in importance; the butyl alcohol—acetone fermentation is now being harnessed to the commercial production of hydrogen. Harington's work on thyroxin is recorded as the most notable advance in the chemistry of the hormones.

A. A. E.

Wireless Loud-Speakers: a Practical Manual describing the Principles of Operation, Performance, and Design. By Dr. N. W. McLachlan. Pp. viii + 139. (London: Iliffe and Sons, Ltd., 1927.) 2s 6d. net.

This book describes in a simple way the main principles used in the design of various modern types of loud-speaker. Both the amateur and the expert will find in it much that is instructive. The musician who judges from the average loud-speaker reproduction of to-day is forced to conclude that at the best it is only fair. The performance of even the best loud-speakers is far from ideal. The musical ear soon detects resonances in the reproduction, and sometimes it soon ceases to give pleasure. It is also necessary that there should be no falling off in the reproduction of notes in the scale having frequencies between 40 and 400 cycles and also in the scale from 2000 to 4000 cycles. In

the former case the bass, and in the latter the upper harmonics, are almost lost. In practice the ear finds a great difficulty in judging which of several imperfect instruments is the best. It seems to be a matter of taste. It has to be remembered that the radiation of sound from a horn loud-speaker is in the form of a divergent beam, the best quality being obtained when the aperture of the horn points directly to the listener. With a cone diaphragm the radiant beam is wider and extends on both sides of the diaphragm. Owing to the focussing effect the reproduction is best with the concave face to the front. In certain cases, however, this is somewhat modified by reflection from the walls of the room.

Entwicklungsgeschichte der mineralogischen Wissenschaften. Von P. Groth Pp. v + 262 (Berlin: Julius Springer, 1926.) 18 gold marks.

This essay on the historical development of the mineralogical sciences is especially interesting in being from Prof. Groth, who has been a leader in these subjects for half a century and has now reached the age of eighty-three years. It is divided into two sections—"Krystallkunde" and "Mineralkunde"—and the period covered is up to the end of the nineteenth century; that is, previous to the recent developments in crystallography due to X-ray methods.

The early history of mineralogy and crystallography are closely interwoven, but now they must be regarded as distinct sciences. Crystallography is no longer an aid only to mineralogy, but also to chemistry and physics—a fact that is well brought out in the present sketch. Besides chapters on geometrical crystallography there are others on physical and chemical crystallography, and on the recognition of the connexion between the form of crystals and their optical properties. The mineral section contains chapters on the crystallography of minerals and the optical determination of rockforming minerals, and on the chemistry of minerals, including the study of their alteration and artificial reproduction. Some account is given of the more important mineral collections in various countries and of the work that has been done on the material so collected. An appendix gives an interesting series of biographical sketches of the more prominent past workers.

The Story of Reckoning in the Middle Ages. By Florence A. Yeldham. With an Introduction by Dr. Charles Singer. Pp. 96. (London, Calcutta and Sydney: George G. Harrap and Co., Ltd., 1926.) 4s. 6d. net.

THE increasing number of teachers who are becoming interested in the history of mathematics will welcome this little book, which is divided into two parts, treating respectively of the abacus and algorism. Admirable diagrams enable the reader to perform simple calculations with the abacus, and the chapters on algorism throw considerable light on the evolution of our modern methods of computation.

## Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE No notice is taken of anonymous communications.]

#### An Aspect of the Biochemistry of the Sugars.

As is well known, the d-galactose configuration may be derived from that of d-glucose by a simple optical inversion at position 4 as shown in the annexed conventional symbols:

$$\begin{array}{c|cccc} H & OH & & H & OH \\ HO & H & & HO & H \\ H & OH & \longrightarrow & HO & H \\ H & OH & & H & OH \\ d\text{-Glucose} & & d\text{-Galactose} \end{array}$$

Although no suggestions as to a probable mechanism of this important transformation have hitherto been advanced, the explanation becomes obvious when certain developments in the theory of the Walden inversion and related simple optical inversions are taken into account. Lapworth, in the course of his studies of the mechanism of the formation and hydrolysis of esters, has pointed out that carboxylic esters and sulphonic esters are normally hydrolysed, and suffer fission generally, at the points shown by the dotted lines:

In harmony with the requirements of this theory, Phillips has found that optical inversion occurs in the fission, for example, the acetolysis of d-benzylmethylcarbinyl p-toluenesulphonate. The results are summarised by the scheme:

with inversion;

$$(II.) \xrightarrow{\text{Ph.CH}_2} C \xrightarrow{\vdots} COR \xrightarrow{\text{Ph.CH}_2} C \xrightarrow{\text{Me}} C$$

without inversion.

In reactions of type I., inversion is normal but not inevitable, since special conditions may induce a direct replacement. Thus there is little doubt that inversions in the carbohydrate group, though not occurring in the hydrolysis of acetates, carbonates, acetone compounds, etc., could be brought about by the formation and hydrolysis of sulphato or arylsulphonyl compounds. The theory which applies to derivatives of sulphuric acid applies also to derivatives of phosphoric acid since, putting it crudely, phosphorus has much affinity for oxygen, and having once acquired the element will be difficult to part from it. Therefore hydrolysis of phosphoric esters will be in

accordance with the scheme  $R = O(PO)(OH)_2$ , and if

the oxygen atom is directly attached to an asymmetric carbon atom, optical inversion should be observed.

No. 3010, Vol. 1207

Bearing in mind, then, the occurrence of hexosephosphates in Nature, it seems certain that the galactose configuration results from the hydrolysis of a glucosephosphoric acid which may occur as such or form part of a larger molecule. An interesting sideissue is the indication of the probable constitution of the glucosephosphoric acid, and the fact that the present hypothesis, permissible on the basis of Haworth's six-ring glucose formula, would be excluded if glucose contained the butylene oxide ring. The reverse change from galactose to glucose will naturally have the same mechanism.

In discussing the matter recently with Prof. W. N. Haworth and Dr. E. L. Hirst, it was pointed out that the above suggestion throws an interesting light on the nature of the pentose in the nucleic acid derived from vegetable nucleo-proteins. has obtained from this source a pentose-phosphoric acid which on hydrolysis yields d-ribose and phosphoric acid and is therefore considered to be a ribosephosphoric acid. It is much more likely to be d-xylosephosphoric acid, the ribose being produced in accordance with the scheme ·

 $(\mathrm{HO})_2(\mathrm{PO}) \overset{\mathrm{H}}{\overset{\mathrm{OH}}{\overset{\mathrm{OH}}{\overset{\mathrm{H}}{\overset{\mathrm{OH}}{\overset{\mathrm{OH}}{\overset{\mathrm{C}}}{\overset{\mathrm{C}}{\overset{\mathrm{C}}}{\overset{\mathrm{C}}{\overset{\mathrm{C}}{\overset{\mathrm{C}}{\overset{\mathrm{C}}}{\overset{\mathrm{C}}{\overset{\mathrm{C}}}{\overset{\mathrm{C}}{\overset{\mathrm{C}}}{\overset{\mathrm{C}}}{\overset{\mathrm{C}}{\overset{\mathrm{C}}}{\overset{\mathrm{C}}}{\overset{\mathrm{C}}{\overset{\mathrm{C}}}{\overset{\mathrm{C}}}{\overset{\mathrm{C}}{\overset{C}}}{\overset{C}}{\overset{C}}{\overset{C}}{\overset{C}}{\overset{C}}}\overset{C}}{\overset{C}}{\overset{C}}{\overset{C}}}{\overset{C}}\overset{C}}{\overset{C}}{\overset{C}}}{\overset{C}}{\overset{C}}{\overset{C}}{\overset{C}}}{\overset{C}}}{\overset{C}}{\overset{C}}{\overset{C}}{\overset{C}}}{\overset{C}}}{\overset{C}}{\overset{C}}{\overset{C}}{\overset{C}}}{\overset{C}}}{\overset{C}}{\overset{C}}{\overset{C}}{\overset{C}}}{\overset{C}}}{\overset{C}}{\overset{C}}{\overset{C}}{\overset{C}}}{\overset{C}}}{\overset{C}}{\overset{C}}{\overset{C}}{\overset{C}}}{\overset{C}}}{\overset{C}}{\overset{C}}{\overset{C}}{\overset{C}}}{\overset{C}}}{\overset{C}}{\overset{C}}{\overset{C}}{\overset{C}}}{\overset{C}}}{\overset{C}}{\overset{C}}{\overset{C}}{\overset{C}}}}{\overset{C}}}{\overset{C}}{\overset{C}}{\overset{C}}{\overset{C}}{\overset{C}}}{\overset{C}}{\overset{C}}{\overset{C}}{\overset{C}}}}{\overset{C}}}{\overset{C}}{\overset{C}}{\overset{C}}{\overset{C}}}{\overset{C}}}{\overset{C}}{\overset{C}}{\overset{C}}{\overset{C}}}{\overset{C}}}{\overset{C}}}{\overset{C}}{\overset{C}}}{\overset{C}}}{\overset{C}}}{\overset{C}}{\overset{C}}{\overset{C}}{\overset{C}}{\overset{C}}{\overset{C}}}{\overset{C}}{\overset{C}}}{\overset{C}}}{\overset{C}}}{\overset{C}}{\overset{C}}{\overset{C}}{\overset{C}}{\overset{C}}}{\overset{C}}}{\overset{C}}{\overset{C}}{\overset{C}}{\overset{C}}}{\overset{C}}{\overset{C}}{\overset{C}}{\overset{C}}{\overset{C}}}{\overset{C}}{\overset{C}}{\overset{C}}{\overset{C}}{\overset{C}}}{\overset{C}}{\overset{C}}{\overset{C}}{\overset{C}}}{\overset{C}}}{\overset{C}}{\overset{C}}{\overset{C}}{\overset{C}}}{\overset{C}}{\overset{C}}}{\overset{C}}{\overset{C}}{\overset{C}}{\overset$ H OH + H<sub>3</sub>PO<sub>4</sub> d-Xylosephosphoric acid

The circumstance that we are able in this way to regard nucleic acid as a derivative of the relatively widely distributed xylose instead of the rare or unique ribose must undoubtedly be regarded as strongly supporting the thesis advanced. The d-ribose could also be obtained from a d-arabinose-phosphoric acid or from l-lyxosephosphoric acid, but d-arabinose and t-lyxose do not appear to occur naturally, and consequently the assumption of the origin from d-xylose is preferable. Finally, without going into detail, it may be pointed out that a consubtraction of the facts in relation to the theory of hydrolysis and optical inversion indicates that the first stage, involving fission of a bond, in the hydrolysis of a glucoside is the opening of the oxide ring.

## Friction of Solids.

THERE seems to be but very little published information regarding the subject of solid friction, and such as there is is chiefly concerned with the effects of lubrication at considerable velocities and at comparatively low pressures.

I think, therefore, it is worth while to contribute a short note on some experiments which I have recently made, in which the pressure between the solids range from those ordinarily met with in mechanical practice up to the highest which the material can withstand 1 and in which the velocities are almost vanishingly small. A list of the materials tried and of their coefficients of friction is given below.

The point worthy of remark is the small difference which exists between the coefficients for the various metals notwithstanding their strong contrasts in other respects. Another point which seems remarkable is that when the pressure is high, the presence of a lubricant nearly always increases instead of diminishing the coefficient of friction.2

<sup>1</sup> An example of friction at destructive pressures is presented by the driving-band on the projectiles of large guns. The great volume of smoke which 'smokeless' powder produces when such guns are fired consists almost entirely of powdered driving-band, i.e. of finely divided copper

The effect of a 'drop' in the saucer in preventing a cup from slipping is very generally known.

In these experiments a small plate of sapphire was always used as one of the pair of substances the mutual friction of which was to be determined, because, as was found after many trials, where one of the pair was so hard as to be free from any chance of being

The tray A was supported on three steel balls rolling on steel guides, and it was found that the resistance offered to the travel of the tray was less than a ten-thousandth of the load carned by it.

In making an experiment the tray was brought to

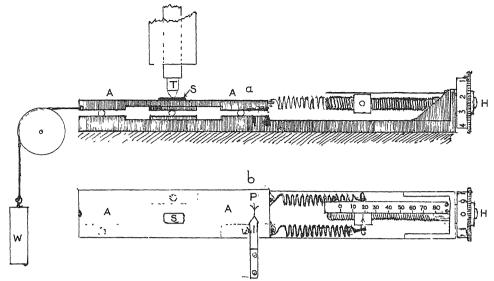

Fig. 1 —Apparatus used in the measurement coefficient of friction—a, side elevation, b, plan, A, tray folling on steel balls, S, sapphire plate, T, test piece, P, zero mark on tray, I, index, II, divided head, controlling spring balance

scratched, the coefficient depended solely on the properties of the softer material.

As mentioned in my letter published in NATURE of May 7, the sapphire plate was carried on a tray

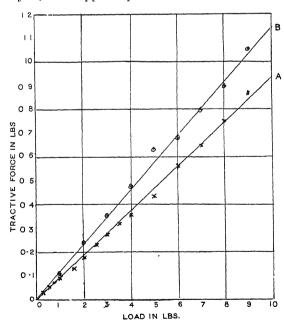

Fig. 2 —Diagram showing the results of two sets of experiments on the coefficient of friction of steel on sapphire

× Individual observations when the surfaces are dry.

• " " in oil

which could be dragged literally under the loaded test piece by the action of a spring balance. The apparatus, somewhat improved, is shown in Fig. 1, a and b.

the zero position by turning the adjusting screw H of the spring balance until the mark P on the tray coincided with the index I

COEFFICIENT OF FRICTION BETWEEN METAL AND

Metal	Coefficient of Friction.	Load,	Pressure
Steel	0 10 0 11 0·11 0·105 0·105 0·114 0·105 0·115 0·115 0·135 0·10 0·111 0 095 0 075 0 10 0 135 0·85 0·95 0·108 0·09 0·108 0·099 0·108	The loads were mcreased by quarter lb, from 0 to 1 lb. " half lb, from 1 lb, to 4 lb " lb from 4 lb to 9 lb.	Pressure = load by measured area of contact.  This ranged up to 300 tons per square unit for steel.  " hmiting pressure for the other metals.

D indicates that the surfaces were clean and dry. L " " lubricated.

To make the zero definite a counter weight W was added to give an initial tension to the springs. The

test piece with its appropriate load was then allowed to piess on the sapphire and the tray (by means of a screw nut shown in the sketch) was shifted slightly in the direction to extend the balance spring. This screw was slacked back and the mark P again brought to coincide with I by turning the divided head H.

The balance reading then gave the force which was just sufficient to cause sliding between the test piece

and the sapphire.

In Fig. 2 one complete experiment is plotted in detail, in order to show the kind of accuracy with which the relation between the tractive force and the load is determined by this method. All the experiments were plotted in the same way, and the order of accuracy is much the same on each. The average results are given in the table on p. 45.

Lubrication was effected by putting a drop of heavy oil on the sapphire before placing the test piece in position. Some very general causes must underlie the approximate equality of all these coefficients, but the explanation would require a knowledge (which does not at present exist) regarding the intimate conditions at solid boundaries.

## The Scattering of Electrons from Single Crystals of Nickel

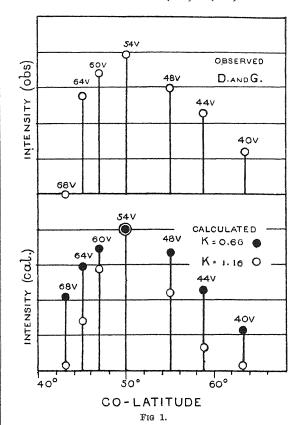

In a letter to Nature (vol. 119, p. 558; April 16, 1927, hereafter cited as loc. cit), Messrs. Davisson and Germer have communicated the results of some very interesting experiments on the scattering of electrons from single crystals of nickel. They show that the distribution of scattered electrons, which have only lost a small fraction of their energy, depends on the voltage, and is in accordance with the symmetry of the crystal. The authors explain their results approximately on the basis of the Einstein - de Broglie theory of the wave electron, in a similar manner to that suggested by Elsasser (Naturwiss., 13, p. 711, 1925) in explanation of earlier experiments of Davisson and Kunsman (Phys. Rev., 22, p. 243, 1923). particular, the explanation given is that electrons of velocity v are scattered by the nickel crystal in very nearly the same directions as those in which an electromagnetic wave of wave-length  $\lambda_s = h/mv$  would be diffracted by the cross grating formed by the uppermost layer of atoms in the face of the crystal—in this case, a (111) face which has been etched by vaporisation.

The alteration in intensity (with varying voltage) of the reflection with maximum at 50° in the {111} azimuth for 54 volt electrons [loc. cit., Fig. 1] is not explained by diffraction at a cross grating. another control which brings out the one reflection as a maximum with the partial suppression of the neighbouring ones. The control is not the complete one which would be exercised by a space lattice. This would entirely suppress all reflections but the maximum. The necessary degree of control would be provided by the influence of a second cross grating lying beneath the first. The observed position of the maximum (i.e. at 54 volts,  $50^{\circ}$ ) can then, however, be explained only by the assumption of a spacing between the two gratings equal to  $Ka/\sqrt{3}$ , where K=0.66 or 1.16 and  $a/\sqrt{3}$  is the normal spacing of the {111} planes of a face-centred cubic lattice of constant a. At these distances the diffracted beams from the two layers are in phase for 54 volts. The two factors two layers are in phase for 54 volts. differ from one another in corresponding path length by one wave-length.

It must be pointed out that the factor K is not quite

the same for all reflections. The calculated maximum intensities for the various voltages in the neighbourhood of 54 volts for the above values of K are shown in the figure, compared with the observed maximum intensities [loc. cit. Fig. 1]. (No corrections have been applied for general scattering.) The positions of the maxima agree with those observed within the error of reading of the published curve. The agreement in height of the maxima is almost equally satisfactory in the two sets. There is a possible preference for  $K=1\cdot16$ , as the existence or non-existence of a peak may be a better criterion than the comparison of intensities. It may be necessary to take a slight effect from the third layer into account.

The variation of intensity with azimuth in colatitude 50° has also been calculated [loc. cit. Fig. 2]. The ratio of the maxima {111} · {100} has been

calculated to be 4:1; that of the observed values, making allowance for general scattered radiation, being of the order 2:1. This agreement is satisfactory when it is realised that atom factors for the gratings will have to be taken into account.

The reflections in azimuths  $\{111\}$  and  $\{100\}$  for 110 volts are not explained by diffractions in a crossgrating parallel to (111). On the suggestion of Prof. von Laue that faces other than (111) were present on the etched surface, the diffractions from the cross gratings parallel to a few of the most probable subsidiary faces were calculated. The assumption of the existence of faces  $\{\bar{1}11\}$  would explain the reflection in the  $\{111\}$  azimuth, giving a value of  $n(\lambda mv/h) = 2(1.06)$ . The reflection in the  $\{100\}$  azimuth can possibly be explained as a diffraction of the same type in the  $\{\bar{1}11\}$  faces of minute twin crystals, which are rotated through  $60^{\circ}$  on the surface of the main crystal.

It is reasonable to assume that an alteration in the

lattice is to be found near the surface of a crystal. Whether an increase or a decrease takes place seems to be an open question. An application of the electron lattice theory of Haber would suggest that the nickel atoms would be repelled, and the spacing increase (cf. Madelung, Phys. Zerts., 20, p 494, 1919). The point is, however, not very clear. That the surface of an etched crystal is not perfectly plane, and that many faces of the order of ten to a few hundred atoms in extent are present, is also to be expected.

It is not profitable to carry the discussion further on the basis of the results which could be communicated in the scope of a letter to NATURE. ment of these results with calculation seems to indicate that the phenomenon can be explained as a diffraction of waves in the outermost layers of the It also appears, which may be crystal surface. even more important, that a complete analysis of the results of such experiments will give valuable information as to the conditions prevailing in the actual surface of the crystal, and that a new method has been made available for the investigation of the structure of crystals in a region which has up to the present almost completely escaped observation. Calculations on the above lines will be continued when a more detailed account of the experiments is available.

In conclusion, the writer wishes to express his thanks to Prof. M. von Laue for the very kind interest which he has taken in discussing this problem.

### The Origin of Speech.

It is well known that the gestures of articulation which produce the consonants L, T, and K are not always made respectively in exactly the same position in the mouth, and that the exact position is more or less dependent on the vowel with which the consonant in question is associated.

Actually, the consonant gesture tends to be made near the position at which the tongue approaches the palate to form the central onfice between the front and back resonators which produce the required pair of vowel resonances.

Examination of the actual resonance - changes produced by the consonant gestures of L, T, and K, in association with different vowels, showed that the acoustic effect of a consonant gesture varied very greatly according to the position in which it was made.

Thus the initial resonance of L in the syllable Li (lee) is about 4 semitones higher (in my voice) that that of L in lu (loo). Similarly, in the case of ti and tu the difference of resonant pitch is 14 semitones, while between ki and ku the difference may be so much as 20 semitones.

These differences of resonant pitch are much greater than those by which we normally distinguish such vowel sounds as i (eat) and ei (hay), or æ (hat) and e (earth), or A (up) and a (calm); yet we normally hear all these consonants as the same—whatever be the vowel with which they are respectively associated.

The conclusion which was drawn from these (and other) observations was that, in appreciating speech, the human mind is not primarily interested in the sounds—which are due to changes of resonance—but rather in the gestures of articulation by which these changes are produced.

We therefore normally accept, as identical, speech

sounds which may be very different in pitch or in change of pitch, if we recognise that they are made by the same gesture of the tongue—even though that gesture may, for convenience, be made in different positions in the mouth when associated with different vowels.

To test the assumption that speech is essentially a matter of gesture, the attempt was made to 'fabricate' a number of words symbolising such simple actions as to dig, wave aloft, shake (like shaking a mat), stab, scrape, etc. The method of formation was to imitate, with the tongue, a pantomimic gesture, such as might also have been made by hand, and to phonate or grunt while making the tongue-gesture.

The phonetic results of these combined gestures and grunts were submitted to Dr. Neville Whymant, who kindly undertook to compare them with early Polynesian, Melanesian, and Japanese words of similar meaning.

As the result he was able to produce close phonetic counterparts from these languages in the case of 11 out of 12 fabricated words. Thus, for to dig, the fabricated word was tadi or tari—the actual Protopolynesian word is tarn, for wave aloft the fabricated word was ledhl-ledhl or ledl-ledl—the actual word is

To test whether the same principle of word formation had been operative in the Aryan languages, the experiment was made of comparing the meanings of a number of Aryan roots which differed only by a single consonant sound—as, for example, the roots LA, LAS, LAGH, and LAK.

It was found that, in the case of about 130 words thus compared, each separate consonant imported a characteristic element of meaning, and that this meaning was pantomimically related to the gesture by which the consonant was produced.

Thus LA—which is due to the sudden lowering of the tongue from contact with the palate—has the meaning 'to be low'

The consonant S is produced by pressure of the tip of the tongue against the back of the front teeth, so as to make a constriction in the front of the mouth.

S consequently denotes a grip or a bringing to a point in a forward position.

Actually, LAS means 'to glean,' that is, to be low and grip or pick in front of one.

GH is due to a partial closure of the back of the tongue against the back of the throat—the sensation being that of flattening the tongue out in the mouth.

Actually, LAGH means to lie down. K is due to a complete closure (and release) of the

back of the tongue against the soft palate. Actually, LAK means to bend or depress—the

forcible K closure importing the idea of stress.

Similarly, R (made apparently with a reflexed tongue as in Wessex and very generally in the United States) commonly denotes a bending back or surrounding, while L symbolises vertical movement, up or down.

Besides the roots which form comparable series, there were found a large number of isolated wordslike DHIGH to smear, WID to see, DU, DUK, or TUH to lead—which give similar evidence of gestural origin. In the case of WID the lips and tongue appear to imitate the human eye, while in DU, DUK, and TUH the lips make a pointing gesture.

Altogether some 320 roots have been found which

show signs of pantomimic origin.

It would appear, therefore, that human speech began by the performance of sequences of simple pantomimic gestures of the tongue, lips, etc., comparable with the natural gestures (of hands, etc.) which are still made by deaf mutes, and that these gestures were made audible by breathing or grunting.

In this way a single polysyllabic 'word' would denote a sequence of actions (or of actions and related

objects), in other words, a 'sentence.'

Since these results were formulated I have learnt that a practically identical theory was put forward in Sept.-Oct. 1862 by Dr J. Rae of Honolulu, in three articles published by The Polynesian, copies of which I have now seen in the British Museum Library (Press Mark—General Catalogue—P.P. 9899. 6).

Dr Rae's conclusions were drawn from a study of

Polynesian word-formation

It is remarkable that, though Prof Max Muller was acquainted with Dr. Rae's articles (see his "Science of Language," Second Series, 1864, pp. 10 and 89), he did not appreciate their importance, or see the light which they threw on the origin of the Aryan roots and of human speech in general.

## Preliminary Note on a Glow in Hydrogen at High Pressure.

DURING an experiment in which an attempt was being made to get atomic hydrogen by means of an incandescent tungsten filament in wet hydrogen, a quite unexpected glow was discovered The apparatus consisted of a three-litre bulb in the bottom of which there was sealed a tungsten filament from a 300-watt electric-light bulb. The pressures varied from 2 cm. to 35 cm., the hydrogen being generated by the electrolysis of potassium hydroxide. No care was

taken to dry the hydrogen or to purify it.

The glow was observed as follows. The filament was allowed to come to incandescence, the observer very carefully shielding his eye from the direct light of the filament. On extinguishing the filament and then opening the eyes, it was possible to see a weakly luminous ball of vapour, blue in colour, rising from the filament and spreading out into an umbrella-shaped cloud at the top of the bulb. This glow persisted for about a second and then disappeared. The act of disappearance was a characteristic one, the glow appearing to collapse from the wall of the bulb to its centre. The speed with which the glow shot up from the filament increased with increased pressures. Below 2 cm. and above 30 cm. the glow was no longer observed.

It was found that after the filament had been run steadily for about thirty minutes it was no longer possible to observe the glow. However, on letting the filament stand for about ten minutes it recovered its former power to give the glow. We suspect from this that the glow is caused by something which is liberated from the incandescent tungsten filament, the fatigue of the filament being due to the filament's having given up all the carriers of the glow.

When fresh hydrogen was allowed to enter the bulb the filament did not give the glow until it had been flashed about ten or twelve times, after which it recovered its former ability to give the glow.

In order to eliminate the possibility that the glow may have been due to excitation of the hydrogen by electrons from the filament which had been accelerated due to the potential drop along the filament, a filament was used which became incandescent and gave the glow on only 55 volts. This immediately eliminated the above possibility, because the lowest excitation potential of  $H_2$  is at 11 4 volts.

Several attempts were made to photograph the

spectrum of the glow, all with no success. ever, by the use of colour filters it was possible to show definitely that the glow extended at least from 5000 Å.U. to 4400 Å U. Therefore, although there are as yet no photographs, there is very little doubt in our mind as to the nature of the spectrum. think that the spectrum is continuous because it is hard to see how such a weak spectrum can extend over a range of more than 600 Å.U. and be anything else. An attempt is now being made to determine the nature of the carriers of this glow.

Physical Laboratory, The Johns Hopkins University, Baltimore, US.A.

#### Anomalies in the Properties of Long-Chain Compounds.

During the course of an investigation into the nature of adhesion (on which I have been engaged with Prof. J W. McBam on behalf of the Adhesives Research Committee of the Department of Scientific and Industrial Research), it has become evident that many of the properties of certain long-chain compounds become anomalous at (or in the immediate neighbourhood of) the 5th, 10th, and 15th carbon atoms in the chain. This is of theoretical interest in connexion with the form which the carbon spiral assumes in particular homologous series.

As is well known, the combined X-ray data of various investigators lend support to the idea that some form of carbon spiral or zigzag exists in certain long-chain compounds; and on certain assumptions the disposition of the earbon atoms in the chain has been more precisely defined. It is desirable, however, that data other than those of X-ray spacings should be considered in this connexion; for example, properties

relating to the molten state or to solution.

According to the stereochemical view, a continuous chain of five carbon atoms would be expected almost to return on itself; and it is reasonable to suppose that a similar disposition of the carbon atoms would recur at the 10th, 15th, etc., carbon atoms. In this event the properties of similarly constituted compounds might be expected to show at least a tendency to periodicity with increase of molecular weight. Evidence of such a periodicity in the molecular rotatory power of the ethyl-R-carbinols (R=alkyl) was obtained by Pickard and Kenyon (Jour. Chem.

Soc., p. 1924, 1923). From a consideration of such properties as static friction, adhesion, cohesion, surface tension, density of packing and electrical properties of monomolecular films on water, optical activity, magnetic rotation, dissociation constants, toxicity, together with other data, it appears that cumulative evidence can now be adduced indicating that anomalies or turning points exist in many of the properties of certain longchain compounds at (or near) the 5th, 10th, and 15th carbon atoms of the chain. (It is intended to publish the detailed evidence shortly.) The abnormality is usually most pronounced at or near  $C_{15}$ , the anomalies being smaller in the neighbourhood of  $C_5$  and  $C_{10}$ . It is considered that publication of the data may stimulate research into the question of periodicity in the properties of long-chain compounds, quite independently of the various X-ray investigations now in progress.

W. B. LEE.

Department of Physical Chemistry, The University, Bristol, June 20.

## Observations of the Total Eclipse of the Sun, June 20.

THE sense of personal disappointment of the astronomers who were prevented by clouds from observing the total eclipse on June 29 gives place readily to feelings of relief that in spite of persistently bad weather the spectacle was witnessed by many expectant people. As Prof. Turner rightly commented in the Times of June 28, the possible technical gains to astronomers on this occasion would take second place beside the general advantage of the public. On account of the uncertainty of favourable weather, the shortness of

the duration of totality, and the low elevation of the sun at the time, this eclipse was not favourable one for the specialists ineclipse problems.  $\overline{\mathbf{A}}\mathbf{s}$  a possible opportunity, however, for many people to see various the phenomena of a total eclipse for the first and only time of their lives, the occasion justified all the careful preparations made on every side for its occurrence.

Three months ago the railway companies regarded the suggestion that a special train might be run to

a place in the eclipse track as scarcely a business proposition. One company replied that, though the event might be of interest to a few astronomers, the public was not likely to pay much attention to it. Within a few weeks of the eclipse, however, it became evident that a very large number of people intended to get within the zone of totality on June 29; and the railway companies with lines in or near the eclipse track found that they could fill all the trains they could run, or for which convenient stations or sidings were available. In addition to the thousands who travelled by rail, very many more journeyed to the track by motor-cars, and during the night of June 28 there was an almost unending procession of cars driving to the main roads within the track.

Such a great pilgrimage to view an astronomical

phenomenon was in itself most remarkable, and though only perhaps about a quarter of a million people actually saw the glorious shrine of the sun's corona, vet every one within the zone of totality was impressed by the accuracy of the timing of the eclipse (the difference between prediction and observation was less than three seconds) and the eerie darkness of the total phase There was a sigh of relief in the watching crowds when the sky began to light up again after the sudden gloom.

Those of us who are familiar with celestial move-

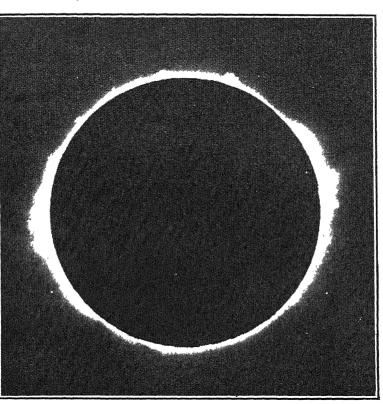

Fig 1.—Photograph of solar prominences and inner corona taken at the Astronomer Royal's observing station at Giggleswick, Yorks, during totality on June 29 Exposure 20 sec., using a 6-in lens of 45-ft. focus by Alvan Clark, kindly lent by Mr James H Worthington.

stand how completely wonderful the prediction of eclipses appears to be to the mind of the general public. Most people have only the vaguest ideas as to the sizes. distances, or motions of the sun, moon, and earth, and to many of them the dark body of the moon seemed to be actually a disc touching the sun. One lady was heard to say that she was afraid the thing would stick upon the sun instead of passing right across. It is true that the periodical press

ments can

scarcely under-

has done much to enlighten the public by means of descriptive and illustrated articles as to the nature and cause of eclipses, and never in the lifetime of any of us has so much space been devoted to an astronomical subject. The Daily Mail in particular took the lead months before the event, and near the day of the eclipse, as well as a day or two later, every daily newspaper made it a leading feature. Reporters and press photographers invaded every station where astronomical instruments were set up, and opinions as to promise or performance were eagerly sought and copiously printed. It is stated in the *Times* of July 4 that 22,000 press telegrams on the eclipse were dispatched from Settle on June 27-29. The London *Evening News* may be congratulated upon a remarkable achievement in this connexion. The Astronomer Royal's

photograph of the corona taken at Giggleswick was developed by ten o'clock on the Wednesday morning, and a representative of the Evening News was permitted to copy the negative He went at once to Leeds by motor-car, and from there his photograph was taken to London by aeroplane, with the result that a reproduction appeared in the Evening News of the same day. By the courtesy of that journal we are able to reproduce the same photograph in NATURE (Fig I). The original negative at the Royal Observatory, Greenwich, shows, of course, more detail, yet the picture here reproduced illustrates how successfully the Astronomer Royal's party took advantage of the good fortune given it during the fine moments of

50

totality.

Though glimpses of the corona were obtained at a few other places, no photographs comparable with that secured at Giggleswick were obtained elsewhere in England or Wales. At Gilling, near Richmond, Yorks, Sir Francis McClean had erected a camera with a lens aperture of 6 inches and focal length of 31.5 feet for the photography of the corona, but he and his brother, Capt. W. N. McClean, as well as Dr. Lockyer, Director of the Norman Lockyer Observatory, who hoped to obtain a photograph of the eoronal spectrum, were prevented by thick clouds from doing anything useful during totality. Similar depressing weather conditions prevailed at most places and prevented observational work, either visual or photographic, by Prof. Fowler at South Kensington, Prof. Newall and the Cambridge party at Aal, Norway, and Prof. Mitchell at Fagerness. It is reported, however, in the Times of June 30 that at Ringebu, in Gudbrandsdal, and at Nyborgmon, in Finmark, weather conditions were perfect and excellent observations were made and photographs taken by Profs Saland and Vegard at the former, and by Prof. Linke and M. Krogness, Director of the Geophysical Institute of Tromso, at the latter.

Whilst sympathising with the many disappointed astronomers who had prepared and hoped for successful observation, it cannot but be felt that the combination of circumstances, such as they were, could not have been happier. In the first place, the Astronomer Royal's party was able to carry through successfully its intended programme, in spite of a serious handicap to the adjustments of instruments imposed by continuous bad weather for a fortnight before the event. Only those who have at least seen something of the preparations required in setting up an eclipse camp can appreciate the skill, concentration, and anxiety involved, and all will rejoice at the Astronomer Royal's good fortune in being at the most favoured place on June 29. At Southport also, a town at which the largest number of people had congregated, a satisfying, although not perfect, view of the eclipse was afforded. Prof. Turner, who has done so much to forward public interest in the eclipse, must-feel highly gratified at his happy selection of Southport for his observing station, to which people gravitated in such large numbers.

An account of the intended programmes of

work proposed at various eclipse stations was given in the Supplement to NATURE for June 18 Work was practicable, however, at three only of these At the Astronomer Royal's camp at stations Giggleswick, the very successful large-scale photograph of the corona already mentioned was taken with an exposure of 20 sec Photographs of the flash spectrum, whilst not completely successful. on account of the lightly-veiled sky, should give useful information. At Southport, the site of the joint expedition from the University and Radcliffe Observatories, Oxford, two photographs were obtained with the astrographic telescope One of these photographs developed during the following afternoon gave a moderately good image of the corona, the other plate being reserved for special treatment at Oxford A pair of polariscopic plates, taken with the similar components of the Abney lens, showed that qualitatively, at any rate, the method employed was successful At Stonyhurst, where the vagaries of the weather were especially evident, the programme arranged by the director could not be carried out owing to cloud, but a visiting astronomer, the director of the Coimbra Observatory, Portugal, was able, in another part of the grounds, to complete two kinematograph films, which it is hoped will show the formation of Baily's Beads. In an aeroplane (kindly placed at the disposal of the Astronomer Royal by the Daily Mail) at a height of 11,000 feet over Darlington, two members of the staff of the Royal Observatory, Greenwich, secured three smallscale photographs showing the corona and its These photographs would have been extensions of special use in defining the type of corona and tracing its extensions if the sun had been completely hidden at all land stations.

The most interesting features of the eclipse appear to be as follows:

The Moon's Shadow.—The approach and retreat of the moon's shadow as a definite boundary were clearly seen by Dr Gerald Stoney from a ridge a few miles north of Richmond, Yorks. To most observers, however, the shadow was simply an increasing darkness. It was noted generally that the increase of light after totality was apparently more rapid than the decrease before totality. The progressive changes of colour as totality approached and passed have been fully described by eyewitnesses in and adjacent to the zone of totality. The most remarkable effects were evidently seen from the air.

Bally's Beads —Several people reported having seen this phenomenon, which occurs immediately before and after complete totality. It is possible, however, that in some cases this may have been confused with the appearance of bright prominences. An account of a spectroscopic observation of Baily's Beads, succeeded by the appearance of the flash spectrum, is given by a correspondent in the Yorkshire Post for June 30.

Solar Prominences and Chromosphere.—The prominences were a striking feature at totality, four or five being visible to the naked eye. The largest of these, near the sun's north pole, was easily seen

by most people, its height was estimated to be 50,000 miles The day previous to the eclipse, Prof Fowler, observing at South Kensington, detected this prominence spectroscopically only sunspots near the sun's limb at the time of the eclipse were placed at position angles 70° and 257° respectively, measured from the north point of the image. The colour ascribed to the chromosphere and prominences by the majority of observers was pink, red, or scarlet It is of interest that the Greenwich observers and their associates in the aeroplane agree in the statement that at a height of 11,000 feet, where the sky was so clear as to be a deep Oxford blue, the colour was a lustrous silver white This divergence of colour estimate might well be a point for observation at future eclipses.

THE CORONA —The type of the 1927 corona is that previously found associated with maximum sunspot activity In shape it resembles that of the 1905 corona (An article dealing with the forms of the corona and their origin was contributed by Dr W J. S. Lockyer to NATURE for June 18, p. 93.) A remarkable feature of the 1927 corona was the brightness of the inner zone One or more extensions were seen, the estimated length for the longest being about 12 solar diameters

We are glad to be able to publish the subjoined details of observations made at various stations

#### GIGGLESWICK.

The Royal Observatory observers at Giggleswick were Messrs Davidson, Jackson, Melotte, and Woodman They arrived a fortnight beforehand in time to meet their instruments, which had been sent from Greenwich by Admiralty lorry. were joined later by Messrs Greaves and Horrocks, and on June 24 by the Astronomer Royal site kindly placed at their disposal by the governors and headmaster of Giggleswick School was a field behind the chapel, from which the morning sun was seen over a hill rising to an altitude of  $4^{\circ}$  to  $6^{\circ}$ . On the morning of the observers' arrival, the sun was seen in a perfectly clear sky at the time of the eclipse, but for thirteen successive days was invisible at this time. During this fortnight rain and wind hampered the observers, but the greatest trouble was the absence of any continuous spells of sunshine This made the final adjustments of the spectroscopes very difficult and somewhat uncertain.

On the day of the eclipse the observers were kept on tenter-hooks, but the sun was visible in a slightly hazy sky for 10 minutes before the total phase. Mr. Horrocks had a chronometer and called out, from the calculated times,  $10^{\,m}$  .  $5^{\,m}:2^{\,m}:1^{\,m}:$  $50^{\rm s}:40^{\rm s}:30^{\rm s}$   $20^{\rm s}:10^{\rm s}$  before totality. The commencement of totality was 3s before the revised predicted time. This was observed by the Astronomer Royal and coincided with the time when Mr Davidson, watching the image, cried 'Go.' Mr. Horrocks from this zero counted seconds.

The duration was 23<sup>s</sup>.

Dr. Jackson exposed a plate in the 45-foot camera from 1s to 21s. A very sharply defined picture of the inner corona on the large scale of 5 inches to the sun's diameter was obtained. The extension is not great, but the detail is very fine.

The spectra of the 'flash' were only partially successful

The observers in the aeroplane provided by the Daily Mail were Messrs Greaves and Witchell of the Observatory staff and Mr. Hargreaves, an amateur astronomer who has been very successful in photographing faint comets. On his advice, hyper-sensitised panchromatic plates were used. With these, three photographs were taken with exposures of  $\frac{1}{13}$ s,  $\frac{1}{10}$ s,  $\frac{1}{30}$ s. The plates show the extension of the corona well, but the longer exposures are affected by shake. The success of this party was due in great part to the magnificent piloting of Capt. Barnard He found a hole in the high alto-stratus clouds and kept the aeroplane in it at the critical time.

The third Greenwich expedition was not so fortunate The Hydrographer kindly arranged for the survey ship H.M.S. Fitzroy to be in the belt of totality during the eclipse Messrs. Edney and Chamberlain took cameras of 27 m. and 20 m. focal length working at F/4.5 and F/5.6 respectively. But the sky was completely covered and nothing could be done

There were no less than 100,000 visitors to the Settle and Giggleswick district who obtained a magnificent view of the eclipse. Among them were a number of boys and girls from West Riding towns like Huddersfield and Keighley. The educational effect of this unforgettable sight is not the least valuable result of the eclipse F. W Dyson.

I observed the eclipse at Giggleswick from a point in the Chapel Field a few yards to the west of the Royal Observatory party. With me were Messrs R. W. H and J Davies, who assisted me greatly in the erection and adjustment of my The only photographic work atinstruments tempted was with a small home-made slitless spectograph fitted with a transmission grating mounted on a prism. The clear aperture was  $l_2^1$  mehes, and the spectrum was focussed by a spectacle lens of 32 inches focal length. The scale of the spectrum thus formed on the plate was about 500 Å U. to the inch. The plate used was a super speed panchromatic, made and kindly presented by the Imperial Dry Plate Company. The speed was estimated by the makers at about 1250 H. & D., and the sensitiveness extends well down into the red, to about  $\lambda7500$  A half-plate was used, and this included about 5 inches of the red end of the spectrum, from  $\lambda 5000$  to the limit above stated. Fairly satisfactory photographs of the flash spectrum were secured at both second and third contacts, exposure at the latter being made by Mr. J. Davies  $\dot{H}_a$  and  $D_3$  are shown as large arcs, the former more than  $180^\circ$  in extent, and there are about a score of reversed metallic lines, mostly in the green; but the plate has not yet been examined in detail.

The majority of totality was devoted to a simple visual scrutiny of the corona with a 3-inch Merz comet-seeker having a power of 17 and a field of 3° 10'. With this instrument the intense brilliance of the lower corona was very striking. It certainly

greatly exceeded the intrinsic brightness of the full moon and seemed to approximate to that of an incandescent mantle. The colour was pure silverwhite, while that of the prominences was rose-pink, or perhaps more nearly cerise The four principal rays of the outer corona seemed to be arranged fairly symmetrically round the disc, and the general appearance was that of a typical maximum corona These rays were very much fainter than any part of the lower corona, but could be traced out to at least a full diameter of the moon. More than one was observed to exhibit a double curvature of outline, and in all there was a marked tendency to radial striation or subdivision. The rays seemed scarcely so white as the lower corona. Instead, they appeared slightly cream coloured, but the somewhat hazy sky may have had something to do with this

At third contact I moved the telescope so as to place the reappearing crescent just outside the field of view. The lower corona and prominences were then still conspicuously visible and remained so for at least half a minute. After this, as the light increased, the corona became gradually fainter, besides growing narrower through the encroachment of the moon's disc, but it could be clearly held until 3 minutes and 5 seconds after third contact This moment corresponded to a 94 per cent. obscuration of the sun. There was much absorption and scattering of the sunlight by haze, and the sky against or through which the corona was seen was very bright Had the atmosphere been transparent and a somewhat higher power been used. I feel fairly confident that I could have seen the corona for at least another minute, and possibly a little longer still. In any event, my observation seems to lead to the interesting conclusion that, given clear weather and a suitable instrument, the lower corona could have been seen at this eclipse from practically every part of the British Isles. Certainly from places near the zone of totality, such as Manchester, Leeds, and Newcastle, it would have been a conspicuous object. W. H. STEAVENSON.

### SOUTHPORT.

The members of the Oxford expedition, Prof. H. H. Turner from the University Observatory, and Dr. H. Knox-Shaw and Mr. H. G. S. Barret from the Radcliffe Observatory, arrived at Southport on June 22, and immediately commenced setting up their instruments in a cycle shed of the King George V. School, which with the ready assistance of the Southport Director of Works was quickly converted into a comfortable observatory. As mentioned in NATURE of June 18, the instruments consisted of the astrographic object-glass of the University Observatory with a portable tube, fed by a 16-in. ccelostat, for direct photography of the corona; and the two components of a 4-in. Dallmeyer doublet (the Abney lens), each of 5 ft. focal length, with two cameras containing plates of plate-glass, blackened at the back, just within the focus, reflection off which polarised the

light in two directions at right angles. These cameras were fixed on an equatorial mounting

The weather was almost uniformly bad during the week of preparation. The instruments were set up approximately in azimuth by means of an excellent plan of the shed prepared by boys of the school, and accuracy to within about a degree was secured in this way. The collostat commanded only the morning sky, and a glimpse of the sun on the morning of June 25 provided the means of its final adjustment in azimuth. Intermittent sights of the sun on June 28 enabled the collostat clock to be rated. As there were no clear nights, the focus of the three telescopes was determined in the school dark-room by a photographic autocollimation method

On the night before the eclipse there was a short interval when the stars were clearly visible, but it clouded up before dawn and there were no patches of clear sky again until the following afternoon. Throughout the period of the cclipse there was a uniform sheet of thin cloud over the sky and considerable lower cloud as well, from which the sun was fortunately clear from 5 h 10 m. (summer time) until about a quarter of an hour after totality, except for a few anxious minutes after six o'clock, when it was almost entirely absorbed. Through this thin cloud exposures of 5 sec. and 2 sec. were made with the astrographic telescope, and a plate was exposed in each of the polariscopic cameras simultaneously for 18 sec.

The latter plates, on which photometric wedges had been impressed at the Clarendon Laboratory, with the kind co-operation of Mr. I. O. Griffith and Dr. G. M. B. Dobson, have been developed, and show differences which seem definitely to be due to polarisation in the corona. It is doubtful whether they will prove of any photometric value owing to the presence of cloud, but it is gratifying to find that this simple and inexpensive method of obtaining photographs of the corona in polarised light, which should be within the reach of amateurs, promises to be successful The 2 sec. exposure with the astrographic telescope was also developed at the school. Although weak, it shows a narrow corona and several prominences, one of them showing a distinct arch. The 5 sec. exposure with this camera was taken back to Oxford to have a wedge impressed on it before development. All the plates show absorption by cloud over the lower limb of the sun.

The observation of the time of second contact indicates a correction to the predicted time of minus 2 or 3 seconds, but this, as in the case of the observation made at Giggleswick, will require confirmation, when the accurate position of the station is determined. A number of persons saw several prominences quite distinctly with the naked eye.

The headmaster (Mr. G. A. Millward) and the staff of the school, and the Mayor and Corporation of Southport, gave every assistance in their power. For the observations at totality the expedition was assisted by Mrs. Turner and Mr. E. B. Knobel, who with fans made the exposures at the two

instruments; by Mr. J. H. Reynolds, who attempted without success, as did Mr. Barrett, to observe the flash spectrum with a direct-vision spectroscope; by Messrs D. C Leech, R Thompson, and C Woodham, masters at the school, who worked the apparatus which provided the wireless time signals from Greenwich and called out the seconds of totality, and by several boys of the school, who booked the times of the various exposures

## Meteorological Observations.

The maximum of wind velocity occurred at 5 28 or 5 29 G.M T, and the maximum 'backing' of wind direction at 5.30 The reduction in velocity was only 2 or 3 miles per hour, namely, from about 6 to about a 4 miles per hour wind, the recovery being the same. The backing of direction was 28° (from a point 146° from north through east to 118°), and the recovery afterwards practically as much.

Temperature fell only 0°4 F. by the M.O thermograph in the Stevenson screen, but 0°9 by the dry bulb of the Assmann aspirated psychrometer. The minimum occurred at 5 34.

The wet bulb fall was  $0^{\circ}$  6 by the Assmann At 5.35 the dry and wet bulbs were only  $0^{\circ}$  9 apart (dry =  $47^{\circ} \cdot 9$  and wet =  $47^{\circ}$  0)

The open-scale barogram shows nothing whatever that can with any certainty be associated with the eclipse.

The grass minimum temperature (by a special thermometer as sensitive as a mercurial one) was 44°8.

Not the slightest char was made on the card of the sunshine recorder all the morning

Joseph Baxendell.

#### DARLINGTON

As I was one of the fortunate few who saw the eclipse on June 29, a brief account of my experience may be of some interest I spent the previous night at Darlington with my party, and a little before 5 30 we went out into the streets in a quiet part of the town. The eastern sky was cloudy, and it was some ten minutes before we could locate the sun, but at last, about 545, there was a break in the clouds and it was seen that the moon had already bitten, so to speak, a fairly large crescent into the disc. Clouds were continually passing, but at intervals we saw the gradual progress of the moon across the sun's face. As the time of totality approached, a mass of cloud advanced and completely obscured the sun, and after 6.20 an extraordinary pall of darkness fell upon us, which we took to mean that totality had begun. We had all but given up hope of seeing what we had gone so far to see, when suddenly the sun disengaged itself, and we saw the black disc of the moon with a fiery belt all around it, and then bursting out from the top right-hand corner came a flash of blinding light which seemed to take the form of two ovoid excrescences. Immediately afterwards, more cloud came up through which we could just make out a thin sickle of light on the right of the moon, and then we saw no more But our effort had been well rewarded.

George A. Macmillan

#### EDINBURGH

Preparations were made at the Royal Observatory, Edinburgh, for observing the 'flash' during the partial phase. The great solar spectrograph with 40-ft focus O.G and Rowland concave grating of  $21\frac{1}{2}$  ft radius was adapted for the purpose by introducing a right-angled prism in the beam so that the tip of the cusp could be rotated tangentially to the slit. The weather, however, proved unfavourable The crescent of the sun was glimpsed at maximum phase (0.98) through low, rainy cloud, but not for long enough to turn the spectroscope upon it, even visually.

R. A. Sampson

#### STONYHURST COLLEGE

At Stonyhurst, owing to a small cloud covering the sun at time of totality, the plates, which were all exposed according to programme, show nothing with the exception of that on the Dallmeyer portrait lens camera attached to the 15-in. equatorial. The eclipsed sun was slowly emerging from the small cloud mentioned above during the last 4 or 5 seconds of totality, and the result on the plate was a fairly complete ring of the chromosphere, the prominences on the west limb, and a trace of the corona to about one-third of a solar diameter beyond the prominences.

TIMES OF CONTACT.—At time of first contact the sun was partially immersed in cloud and no obser-

vation was possible.

The time of second contact, 5 h. 23 m 58.9 s. G.M T., was well determined by Father Rowland observing through a prismatic monocular magnifying 8 diameters, the Rev. J. Lawrence, S.J., timing with the Frodsham half-seconds chronometer, of which the correction had been determined from the Greenwich radio signals at 4 h G.M.T. The rapidly diminishing solar crescent was distinctly though faintly seen through the cloud, until

its quite sudden disappearance

The third contact was unfortunately not so well determined. When the crescent disappeared, there was absolutely nothing left to hold in the field of view, and though the observer tried to keep the instrument directed to the assumed position of the sun, it actually drifted off, and the first intimation of the end of totality was the appearance of the emerging crescent, seen with the other eye, without instrumental aid, and immediately the signal 'stop' was called. The time was clearly late, the observer estimating the error as about  $1\frac{1}{2}$  sec. Father O'Connor, who was operating the 19-ft. prismatic camera, and was carefully observing for the first reappearance of a Baily Bead, with the view of obtaining the second 'flash,' closed down just one second before the signal 'stop' was given. Applying a correction of  $1\frac{1}{2}$  sec., the time of third contact works out as 5 h. 24 m. 20.9 s., giving a duration of totality of 22 sec.

The times of second contact and of duration had

been worked out by Dr. Crommelm as 5 h. 24 m  $\,$  0 s., and 22 sec respectively

MAGNETIC RECORDS—In accordance with the request of the Permanent Joint Eclipse Committee, quick runs of 4 hours' duration were made on the magnetographs from 4 h. to 8 h G.M T on June 28, 29, and 30. The curves obtained are beautifully clear, and throughout the periods of the quick runs on all three days the magnetic conditions were exceptionally quiet, and so were well suited to bring out any deviations from the normal effect of solar radiations as affecting magnetic conditions the curves show that there was not the slightest variation at or near the time of eclipse, it appears to be clearly established that the screening action of the moon is without magnetic effect under these conditions Whether it would produce any diminution of disturbed conditions remains an open question

METEOROLOGICAL —The barometer was steadily falling all the time from 29 342 m. at 4 15 G.M.T. to 29 326 in at 6.0 G.M T.

Readings of the thermometer were taken at every 15 minutes, starting at 4.15 G.M.T. The readings were .  $54^{\circ}.3$ ,  $54^{\circ}.5$ ,  $54^{\circ}.6$ ,  $54^{\circ}.4$ ,  $54^{\circ}.3$ ,  $54^{\circ}.3$ ,  $54^{\circ}.7$ ,  $56^{\circ}.5$ . The thermograph showed practically no variation.

Further to my earlier communication, it may be of interest to note that the time of second contact was confirmed by an independent observation made by the Rev. J. O'Hea, S.J., working with a second chronometer at a station 23 chains due south of the first station, who obtained the time of second contact as  $5^h$   $23^m$  58  $5^s$  G.M.T. By interpolation from the data on the B.A.A. Eclipse Map, the time at the second station should be  $0.36^s$  earlier than at the first station, and applying this correction the time reduced to the first station becomes  $5^h$   $23^m$  58  $86^s$ , which is in striking agreement with that actually observed there

It had been intended to observe the times of contact by noting the instant of the reversal of the Fraunhofer lines of the spectrum as the moon covered and uncovered the photosphere. For this purpose a transparent Thorp replica grating of about 14,000 lines to the inch was fitted in front of the objective of the prismatic monocular. With this instrument a beautiful spectrum was obtained, and as the solar crescent waned the principal Fraunhofer lines could be distinctly seen as curved arcs, but as totality approached the spectrum became so faint owing to the interposition of the small cloud mentioned in my previous communication, that it was realised the method might fail from lack of light, and the instrument was therefore turned direct on to the diminishing crescent.

E. D. O'CONNOR.

## RICHMOND, YORKS.

The expedition from the Norman Lockyer Observatory took up its position at Olliver Ducket, near Richmond, on June 19, and commenced operations in setting up the instruments; and the

work was completed and all in order two days before the eclipse. For the first few days the weather was farrly fine, but after that it became very wet and windy and made it very difficult to erect the tube of the 30-ft coronograph. Very little work could be done on June 21 owing to a gale, which necessitated everything being anchored down securely.

Observation of the sky every morning at the time and in the direction of the eclipse showed that on three occasions it was perfectly clear, two days thin clouds were present, and for the rest totally overcast. Three mornings previous to eclipse day thick cloud intervened

Sir Francis McClean and Capt. W. N. McClean with their staffs were each operating three instruments, and the writer with his staff four instruments. Three members of the Observatory Corporation were also located on our site and were employing one instrument each.

On the morning of the eclipse the sun when just above the horizon appeared as a red disc, but soon became hidden by clouds. At 5<sup>h</sup> 10<sup>m</sup> the clouds seemed to be breaking up and patches of blue sky appeared in the south, from which direction the light wind was coming. The valley mists appeared to be rising and dissipating, and the prospects looked hopeful at about 5<sup>h</sup> 35<sup>m</sup>

At 5<sup>h</sup> 50<sup>m</sup> the conditions seemed to be more promising, and at 6<sup>h</sup> 0<sup>m</sup> the partial phase was well seen in clear sky for a few minutes. At 6<sup>h</sup> 7<sup>m</sup> heavy clouds obliterated the sun from view, and I then thought that we should not see the sun again. This turned out to be the case. At 6<sup>h</sup> 15<sup>m</sup> the conditions were hopeless, and the sun was not seen again until half the partial phase had passed.

The system of time signals was carried out very efficiently by Capt. McClean's assistant, Mr Chapman. In addition to preliminary signals, every minute was called out, beginning at four minutes before totality, and every second for thirty seconds before totality. The greatest darkness seemed to arrive at the moment 'one second' was called. The majority of the observers carried out their programmes according to schedule, although it was known that no results could be secured During the total phase it was very dark, but no doubt the heavy clouds were responsible for this to a great extent.

It is pleasing to place on record the fact that every assistance was given to the party whenever it was desired, and special thanks are due to Capt. Nelson Rooke, acting for the Marquess of Zetland, who did all in his power to make the expedition a success.

WILLIAM J. S. LOCKYER.

#### REETH (SWALEDALE).

The Armstrong College party consisted of Messrs. H. W. Davis, T. Russell Goddard, G. R. Goldsbrough, Wilfred Hall, G. W. Todd, and Stanley Todd. The site selected was Gointar Lodge, near Reeth, Swaledale. The equipment consisted of a 5-inch photo-visual objective mounted in a fixed horizontal position, and served by a cœlostat; a

14 cm. photographic objective in an equatorial mounting and three fixed cameras of shorter focal length for instantaneous exposures These were all intended for photographing the corona were also a Hilger two-prism stellar spectrograph mounted equatorially with a Zeiss objective, an objective prism with 3-inch objective mounted equatorially, and a grating and fixed camera served by a small coelostat. These were intended for flash spectra and, if possible, coronal spectra.

During the early phases there were broken clouds which allowed occasional glimpses of the sun. There was a clearer view just before totality, and the last thin crescent was distinctly seen with The crescent Baily's Beads forming at the cusps also seemed to be tremulous Then just as totality was about to begin a thick cloud covered up the sun,

and no plates could be exposed.

Reeth—10 miles up Swaledale, west of Richmond -had moderate eclipse luck The day before looked most unpromising, but with some hope at night in spite of the gloomy weather forecast. At 3.35 AM Jupiter was visible and there were wide areas of clear sky. On arrival at our observation post, on the ridge above Marrick Abbey, a couple of miles east of Reeth, the eastern sky was covered by dense cloud, but there were clear areas to west Breaks in the clouds gave a view and south-east of the sun when a fifth covered; we saw it a dozen times, the last being about 4 minutes before totality. Then the cold seemed to condense cloud in the eastern gaps and we saw the sun no more. Eight diverging rays marked its position. They vanished suddenly at totality, and reappeared as suddenly at its end. The inky darkness below the sun was impressive, but we saw no advancing shadow from the west, and the western sky was much lighter.

On somewhat higher ground to the south, on the edge of Wensleydale above Leyburn, experiences were much the same—ten views of the sun through gaps and its disappearance 4-5 minutes before Observers on the plateau to the north of us enjoyed only one early view of the sun. Mist

rested on some hills to the south-west.

J. W. GREGORY.

#### COLWYN BAY.

Although dense clouds veiled the whole of this phenomenon from Colwyn Bay, it was possible to time the end of totality within a second or so by the passage of the edge of the moon's shadow (which was well defined on the clouds) over the known place of the sun. The time, using the wireless signals, was 5h 23m 55s U.T. Both the descent of darkness and the return of light happened several seconds before the predicted times, since these were produced by the shadow on the cloud layer above us, and as the shadow was only some 10° from the horizontal position, it reached a particular cloud several seconds before it would have reached the point on the ground vertically

below The colour of the sky during totality was a beautiful blue with a purplish tinge darkness was considerable, being increased by the thick layer of clouds A. C. D. CROMMELIN.

The Royal Irish Academy party undertook a programme of observations on atmospheric electricity at the old telegraph station at Llysfaen, near Colwyn Bay. On the mornings of June 28, 29, and 30, from 4 20 A.M. to 8 30 A.M., continuous measurements were made of the atmospheric potential gradient, of the atmospheric conductivity, positive and negative, and of the concentration of condensation nuclei. No effect attributable to the solar eclipse was detected, but any moderate change would have been masked owing to the disturbance in the atmospheric electric elements caused by the rain which fell during the eclipse Apart from the question of possible effects due to the eclipse, the examination of the results obtained is expected to give useful information in connexion with the equilibrium of atmospheric ionisation.

J J NOLAN.

The astrophysical observations which were hoped for at Llysfaen, near Colwyn Bay, were completely spoiled by clouds. No glimpse of the sun was obtained on June 29 before, during, or for several hours after the time of eclipse. One member of the party, however, who carried out experiments on wireless reception, obtained results which may be of value, and his statement is subjoined.

HERBERT DINGLE.

The special transmissions from Eindhoven, on a wave-length of 30.2 metres, were received by means of a short wave receiver, and measurements were made of the variation in signal strength over the period 4.30 to 8.30 B S.T. on the morning of the eclipse, and of the day before and after. On June 29, generally similar variations to those obtained on the other days were observed for some time before totality. During totality, however, the signals faded out completely, and the station was only heard very faintly and irregularly from then until after 7 A.M., when the reception began to improve again. The results for the normal days before and after the eclipse showed no such marked fading over the same period (6.23 A.M. to 7 A.M.).

## CRICCIETH.

Criccieth eclipse station had very heavy rain during all phases of the eclipse, and no photographs were obtained either of the corona or of the spectrum.

Dr. J. H. Shaxby, of the National School of Medicine, Cardiff, assisted by Mr. Deniol Williams, of Aberystwyth University College, took photometric measurements throughout the eclipse with particular attention to the period from 6.20 to 6.30 Summer Time, and I have asked Dr. Shaxby to send NATURE certain of the results of his work. The curve is an interesting one, although not so valuable perhaps as it would have been had we been favoured with good weather.

It was a glorious quest well worth the effort, and all the party thoroughly enjoyed the work in

spite of the disappointment

We had a 21-inch siderostat and were working from it with a 6-inch mirror of 7 ft focus, a 6-inch mirror of 24 inches focus, a two-prism objective prism spectroscope for the flash spectrum, and a grating spectroscope for the infra-red end. All our spectrum plates were special neocyanine ones with the ammonia doping to make them supersensitive

A. Taylor.

#### SNOWDON

On the morning of the eclipse a whirling mist of cloud slashed with streaks of rain narrowly restricted the range of vision on Snowdon summit but did not quench the sunlight, which it uniformly diffused. The view-point which I had chosen the day before was not upon the cairn or the platform which, with buildings, artificialise the highest peak, but a narrow spur of rugged rock about fifty feet lower, overhanging precipitous descents on either hand of which the bottom was undiscernible on either day Pointed battlements of rock a few feet distant fenced the turret of my outlook, beyond, the luminous obscurity of cloud reached from the zenith nearly to the nadir. I was alone, and no human form loomed into sight through the mist.

The wildness of the scene was enhanced by the veering and backing of a gusty wind which drove

the pelting rain upon the crags, and its monotony was unrelieved during the partial eclipse, for the murk of the morning seemed but a thickening of cloud. At length, on a sudden, there was a shutting-off of light as if a curtain had been quickly drawn part way across the window of heaven. Before I could recover from the start, a second and greater darkening occurred, as if the window had been completely curtained, and all around was the blue-blackness of night. The jutting rocks were blackest. The atmospheric background, above and below, was uniform in tint, no longer showing whirls of mist or stretches of rain.

The condition of an unusually sombre night had continued for a sufficient number of seconds to let the mind begin to broad, when I was awakened as from a dream by the dawn of a new day, miraculous from the suddenness of its light and remarkable for the quick change of tint to a ruddy The brightening of this first drawing-back of the curtain was much greater than the darkening of the first partial closing Before surprise had passed there was a second flood of light, and one felt that the window of heaven was now completely uncurtained There were no more phenomena, for ours was a total eclipse without the incidents of the partial phase. The narrowing of the view was lamentable, but the concentration in time to one breathless half-minute was extraordinarily dramatic, and the solemnity of the surroundings amply compensated for the discomforts of a lofty and exposed situation. VAUGHAN CORNISH.

## Archæological Work at Gerar.

By Sir Flinders Petrie, F.R.S.

T had long been desirable to obtain a more exact scale of dating in the archaeology of Palestine. For this purpose the Egyptian connexions were needed, and the British School of Archæology in Egypt therefore settled last winter upon the mound of the city of Gerar, nine miles south of Gaza, almost in the desert. An area of about an acre was cleared, to thirty feet deep, through six superimposed layers of building from 400 to 1500 B.C. Each chamber found was lettered on the plans, and each object found was given its chamber letters and foot level. The planning was continuous, and 2000 objects were drawn in outline for publication The record is therefore complete, without needing notebooks or card catalogues. The date of each of the six layers of building could be ascertained within ten years by the external history; the rate of accumulation happily proves to accord with the time scale throughout, to within a foot,

Iron furnaces of about 1200 B.C. were found, and by them were very large tools, as a pick of seven pounds weight, hoes, and plough points. The ore was probably hæmatite, resulting from decomposition of pyrites from the Beersheba basin. Iron knives were made from 1350 B.C., probably the earliest manufactured iron known. The flush of gold named in Judges viii. is apparent in the

many earrings and a gold frontlet which were all of that age, while none was found of later times. The influences were from the east and central Asia under Shishak, 900 B.C., but from Italy and Cyprus in 800 B.C. The business of the city was making the arms and clothing for the north-west tribes of Arabia, as now in modern Gaza The position was important as being on the road from Egypt to the Judxan hills, and also as commanding the coast road; hence the Egyptian kings fortified the place whenever they occupied Palestine. The Persians also made this an army base of supplies for invading Egypt, building large granaries to hold enough corn for 100,000 men for two months. This fertility of the plain in good seasons accords with the great number of flint sickles found, of about 1800 to 1400 BC., and the hundredfold crops named in Genesis xxvi. The Philistine settled here was apparently a corn-factor to collect grain for supplying Crete, like the Philistine at Ekron in the middle of the Shephelah corn land.

It appears that the coast must have been submerged as much as 125 feet in late Roman times, and recovered later. There are stratified silt deposits up to that level at Gerar containing Roman pottery throughout, and three miles nearer the coast the stream cuts through 50 feet of these

deposits with Roman pottery from base to top The top plane is at the same level at both places. As the valley is two miles wide and fifty feet deep, any artificial dam is improbable, and the silting must therefore have been due to an estuary reaching up to 125 ft. There are great deposits of recent shells on hills by the coast up to about 80 ft The Egyptian movement at Alexandria was at least 40 ft of submersion, and a later recovery of 18 ft. This corner of the Mediterranean needs an historical survey, including the pottery and other remains. The collection brought to London will be on view at University College, Gower Street, until July 16.

#### News and Views.

It is announced that the Secretary of State for the Colonies has appointed a Committee "to formulate practical proposals for submission to the Colonial Governments to give effect to the resolution for the Colonial Office Conference on the subject of Colonial Agricultural Scientific and Research Services " These proposals are to "include a scheme, based on contributions to a common pool, for the creation of a Colonial Agricultural Scientific and Research Service available for the requirements of the whole Colonial Empire for the support of institutions needed for that purpose, and for the increase of research and study facilities in connection with specialist services of the Colonies generally." The committee is thus constituted · Lord Lovat, Parliamentary Under-Secretary of State for Dominion Affairs (chairman), Mr. W. Ormsby-Gore, Parliamentary Under-Secretary of State for the Colonies; Sir Graeme Thomson, Governor of Nigeria; Mr. A. S. Jelf, Colonial Secretary, Jamaica; Mr. O G. R. Williams, Assistant Secretary, Colonial Office; Major R. D Furse, Private Secretary (Appointments) to the Secretary of State for the Colonies; Sir J. B. Farmer, Dr. A. W. Hill, Mr. F. L. Engledow, and Dr. A. T. Stanton, Chief Medical Adviser to the Secretary of State for the Colonies.

If reference be made to the second paragraph of the leading article in this issue of NATURE, it will be observed that to this committee has been relegated one part of the more comprehensive task given to the Committee appointed by the Colonial Office Conference at its first session. At that Conference were gathered together official and authoritative representatives from most of the thirty different colonial administrations. The scheme for agricultural research recommended by the committee they appointed involved them in a total annual cost of £175,000, the greater part of which is already a charge on their revenues. The Conference approved the recommendations of the committee, which in the main were those of a Commission on Agricultural Research and Administration in the Non-Self-governing Dependencies, appointed some years ago, the report of which had just been published. General consent might have been obtained immediately, it might be presumed, for some systematic method of determining the contributions of the various colonial governments to the central pool and matters of detail left to the Agricultural Research Council. The appointment of this further committee will inevitably involve more delay in the long overdue reorganisation of the colonial agricultural research and scientific services.

THE Golden Valley is one of the chief beauties of the famous Hindhead district, in the neighbourhood of Farnham and Winchester, and its wild and beautiful slopes, wooded with pine, birch, and hawthorn, and chequered by gorse and broom, make an essential complement to the neighbouring land secured for the people under the National Trust. At short notice the Golden Valley was put up to sale for building plots, but the prompt action of Dr. Marie Stopes in stepping in to purchase the Valley (at the surprisingly low figure of £5650) gave the residents time to form a committee to collect funds which would save the land from the builder. The completion date for the sale was June 30, but the vendors have granted a short extension, and the National Trust, to which the property would be handed over, now issues an urgent appeal for the small sum needful to complete the purchase price. Residents and local sympathisers have played their part, for already approximately £4500 has been subscribed. Less than £1500 is required, and we feel assured that so good a cause need only be mentioned to obtain the support it deserves. It would be a calamity were this spot, where artists, writers, and naturalists have gained inspiration, to become lines of villas. tions to the Golden Valley fund, so marked, should be sent to S H. Hamer, The National Trust, 7 Buckingham Palace Gardens, London, SW.1.

On July 14 occurs the centenary of the death of Augustin Jean Fresnel, the distinguished French physicist who shares with Young the honour of establishing the undulating theory of light. Born at Broglie (Eure) on May 10, 1788, Fresnel was a few years younger than Arago, Brewster, Biot, and Malus, all of whom laboured in the same field. He was educated at Caen; at sixteen years of age he passed into the École Polytechnique, and after being trained as a government civil engineer in the École des Ponts et Chaussées, was employed in various provincial departments. His important scientific work began with his paper on diffraction read to the Paris Academy of Sciences in 1815. Just as Young in England met with opposition, so Fresnel had to face the criticisms of Laplace, Poisson, Biot, and others. Fresnel, in addition to his theoretical work, made practical improvements which led to the adoption of polyzonal lenses in lighthouses adopted first in France and then in foreign countries. Towards the end of his life he acted as examiner to the École Polytechnique, but his various duties proved somewhat too much for his feeble constitution, and he died at

Ville d'Avray on July 14, 1827, at the early age of thirty-nine years. Only a few days before this, he had received at the hands of Arago, the Rumford Medal of the Royal Society, awarded him for "His Development of the Undulatory Theory, as applied to the phenomena of Polarised Light; and for his various important Discoveries in Physical Optics." Some of his memoirs lay unpublished until 1884, the year his memorial was unveiled at Broglie. These were found among the papers of Ampère and relate to electromagnetism. Fresnel's great lenses are preserved in the Paris Observatory.

The thirty-eighth Congress of the Royal Sanitary Institute will be held at Hastings on July 11-16, under the presidency of the Right Hon Sir William Joynson-Hicks, Bart. The lecture to the Congress will be given on July 12, by Sir William Willcox on "Chronic Rheumatism in its relation to Industry," and on Friday evening Sir Henry Gauvain will give an address and show a film dealing with "The Treatment and Training of Crippled Children." The business of the Congress will be carried on in seven sections and six conferences, covering various aspects of personal and public health and hygiene. A special feature of the meeting will be the conference dealing with health resorts, over which Dr. A. Rollier, of Leysm, will preside. Among the topics to be discussed at the Congress are the following: The notifiable infectious diseases of the nervous system; industry and disease; inspection and consumption of food, tubercular infection in milk; treatment and disposal of sewage. Many visits and excursions to places of professional and general interest have been arranged. The Health Exhibition, which is an important part of the Congress, will include exhibits relating to domestic health and comfort, municipal sanitation, etc.

THE provisional programme of the annual meeting of the British Medical Association, to be held at Edinburgh on July 15-23, includes many discussions, several of which are of general scientific interest. These include the following, the section or sections arranging the discussion and the opener's name being given in brackets: the results of insulin therapy in diabetes mellitus (Section of Medicine, Prof. Hugh Maclean) on July 20; immunity (Sections of Pathology and Bacteriology and Comparative Medicine, Dr. R. A. O'Brien and Prof. Carl H. Browning) on July 21; the therapeutic uses of calcium salts (Section of Therapeutics and Pharmacology, Prof. F. R. Fraser) on July 21; the duties of the State in regard to food supplies (Section of Preventive Medicine, Prof. E. Mellanby) on July 21; the structure and function of the spleen (Prof. John Tait) and the influence of internal secretions on sex characters (Dr. F. A. E. Crew) on July 21, and chemical changes accompanying muscular activity (Prof. T. H. Milroy) and hæmolysis (Dr. E. H. Ponder) on July 22 (Section of Physiology and Biochemistry); the historic evolution of disease (Section of History of Medicine, Sir Humphry Rolleston) on July 22. A feature of the meeting

will be the celebration of the centenary of the birth of Lord Lister, a meeting presided over by Lord Balfour will be held in the M'Ewan Hall on July 20, and short addresses will be delivered by Sir W. Watson Cheyne, Bart, Prof. Tuffier (Paris), Prof. Harvey Cushing (Harvard), and Dr. James Stewart (Halifax, Nova Scotia). A museum of relics of Lister will be open throughout the week in the Upper Library of the Old University. The honorary local general secretary is Dr A. Fergus Hewat, 14 Chester Street, Edinburgh.

WE learn from a Daily Service News Bulletin recently issued by Science Service, Washington, that the "dangerous fish tapeworm of Europe," Dibothriocephalus latus, which is adult in man and has become established in the United States, is to be the object of special study this summer by a group of investigators under the direction of Prof. H. B. Ward. The investigation, which is supported by the National Research Council, will be carried out in the extreme north of Minnesota, which is the centre of the infected area. The tapeworm appears to have been introduced into the United States by immigrant labourers in the iron and lumber industries, who not only carried the parasites internally but also imported their favourite dried and salt fish from their central and eastern European homelands. Salting of the fish does not kill the young stage of the tapeworm, and imperfect smoking also leaves the worm alive. There is evidence that the native fishes m some of the northern lakes of the United States may have become infected, and the investigators hope to secure definite evidence on this point and to work out methods for keeping the infection from spreading.

ABOUT two years ago the Astronomical Society of the Pacific proposed to reprint some of the popularlywritten descriptions of topical developments and discoveries in astronomy which from time to time appear in various publications, provided a sufficiently widespread desire for such reprints was manifested by the members. We have now received a batch of nine leaflets of the character indicated, from which it may be inferred that the proposal has been favourably received. They consist of double-leaved pamphlets, about 6 in. by 4 in. in size, containing 1000-2000 words, and the subjects dealt with and the manner of their treatment are well indicated by the titles: "Mira, second largest star, could engulf earth's orbit"; "Why popular interest in Mars?"; "Island Universes"; "The strange companion of Sirius"; "A close-up of the moon"; "How far away is that star, and how do you know?"; "The Magellanic Clouds"; "The Pleiades"; "The Great Nebula in Orion." The notes are written by astronomers of repute, and most of the leaflets contain reproductions of photographs illustrating the subject treated; Dr. Moore's article, for example, on the great nebula in Orion, is accompanied by an admirable view of that object. We congratulate the Astronomical Society of the Pacific on this excellent idea, which, if it meets with the success it deserves, will, we hope, be taken up by responsible bodies in other branches of science. We should like, in fact, to see the project extended beyond the boundaries of scientific societies. Religious and political organisations have long realised the value of the tract as a means of bringing their respective gospels before the public at large, and if funds are available, there appears to be no reason why the gospel of science and of education in general should not be proclaimed in a similar manner. The leaflets before us are admirably suited for such a purpose

British scientific workers tend to be conservative in their reading of the foreign technical press. It is therefore with some pleasure that one notes the increasing vogue of foreign technical abstracts in British journals. The Journal of the Royal Aeronautical Society publishes each month extracts from the scientific and technical press as issued by the directorates of technical development and scientific These are excellent as giving a short résumé in compact form of the most recent work in aerodynamics. In the May and June issues, for example, there is a number of excellent abstracts from the French and German press on the work which is proceeding in these countries on fluid motion. Experimental criticisms have been levelled by H. Benard against Karman's laws of frequency and distribution of vorticity behind an obstacle. The latter, in an excellent reply, points out the existence of surface ripples in Benard's experiments, estimates the effect due to these, and verifies his previous results. A number of abstracts deal with the rate of spread of turbulence in a viscous fluid, while others treat the problem of heat transference from liquids or gases to solid walls, a subject to which Prandtl and Karman have contributed so much in recent years. These abstracts give an idea of the inspired work which is proceeding at various German centres along these lines. It would appear that during recent years the centre of gravity of pure hydrodynamical investigation has definitely shifted to the Continent.

The current issue of the Svenska Linné-Sallskapets Arsskrift (Årgång 10, 1927) is of much historical interest. It is devoted to the publication of papers illustrative of the life and work of Linnæus, delivered at the Swedish Linné Society's commemorative meeting, which took place in his native village in Småland on May 23 of last year, the anniversary of the birth of the great botanist. Much of the material is of biographical rather than of botanical interest. Prof. Robert Fries, chairman of the Society, contributes an account of Linnæus' connexion with Småland, his early life there, and the botanical influence which helped to shape his career. Prof. H. O. Juel and Mr. G. Drake give some interesting botanical and pharmacological notes on Linnæus' "Report on the Medicinal plants growing in Sweden." Mention is also made of his abortive attempt to introduce the tea plant from China. The somewhat complex disposition of Linnæus is admirably analysed by the Rev. E. Malmestrom, who holds a brief for the great systematist's exaggerated self-esteem, and the laudatory terms in which he refers to himself. Shorter articles deal with various topics of local and historical interest.

Prof. Henry Louis, emeritus professor of mining at Armstrong College, Newcastle-on-Tyne (University of Durham), has been appointed president of the Institution of Mining Engineers in succession to Dr. J. S. Haldane. He will take office at the annual meeting in London in November.

DR. WHITMAN CROSS, of Washington, and Prof. A. G. Hogbom, University of Upsala, have been elected foreign members of the Geological Society. Prof. F. X. Schaffer (University of Vienna), Prof. C. Schuchert (Yale University), Prof. F. Slavík (University of Prague), and Dr. E. O. Ulrich (U.S. Geological Survey) have been elected foreign correspondents of the Geological Society.

A RECENT news bulletin issued by Science Service of Washington states that the State of Montana has allocated 60,000 dollars for the erection of an entomological laboratory at Hamilton, Montana, with 25,000 dollars per annum for the next two years for research there. One of the pressing problems to be investigated is Rocky Mountain spotted fever, which is conveyed by a tick. It is hoped that a parasite of the tick may be utilised for its destruction, and so the conveyance of the disease may be prevented.

A NUMBER of useful papers appear in the recently published *Proceedings* of the Chemical Engineering Group of the Society of Chemical Industry, vols. 6 (1924) and 7 (1925). The 1924 section contains four papers, two on crystallisation and two on chemical works costs. A considerable portion of volume 7, containing 17 papers, is devoted to fuel questions, but it includes articles on the internal combustion boiler, the treatment of solvents used in dry cleaning, crushing and grinding mills, aerosols in industry, and other subjects of importance to the chemical engineer. The volume of 200 pages is well illustrated, and it will be valued by all interested in large-scale chemistry.

COMBUSTION engineers have often discussed the possibilities of having central heating stations for supplying steam for the steam-pipe heating of buildings and flats. We learn that 45 miles of mains for this purpose have already been laid in New York, and that more than 7000 million pounds of steam are being sold yearly by meters. The steam is used in addition for electrical generation for lighting and for working lifts in office buildings. Many householders discard their furnaces and buy steam instead of coal. To produce this steam last year 350 thousand tons of the cheapest grades of anthracite and pulverised bituminous coal were used. Recent improvements in the main steam pipes, which carry large quantities of steam long distances, have made this method of supplying heat a rival to electric and gas heating. Somewhat similar methods are used on a smaller scale in other parts of the world.

The "Statistical Report of the Health of the Navy for the year 1924" has recently been issued (London: H M. Stationery Office. 4s. 6d. net.). The returns for the total force show a decrease in the incidence of disease as compared with the three years' average, but a slight increase in relation to 1923. The invaliding and death ratios also show a decrease in comparison with the three years' average. The Mediterranean Station showed the lowest sick rate, and the China Station the highest. Bronchial catarrh caused the largest number of cases (5641) of sickness, and influenza, 2407 cases. As in the Army, tonsillitis shows a considerable incidence with 2602 cases.

Prof Samuel J. Record, of the Yale School of Forestry, has presented to the Smithsoman Institution a valuable collection of plants illustrative of the flora of Honduras, one of the few regions in North or Central America which is still practically unknown botanically. In view of the lack of knowledge of the forest flora of Honduras, it is not surprising that study of the collection has revealed the presence of several new species, a genus new to North America, and several extensions of range. The collection includes many woods of economic importance, and it is probable that much information of value to the lumber industry will result from the study of the economic woods of Honduras which this collection makes possible.

WE have received a copy of the Index of the Faraday Society Transactions, vols. 1-20 (paper cover, 10s. 6d. net; cloth, 13s. 6d. net). The entries have been emphasised in such a way that quick reference is facilitated. For this reason the titles of the papers have in some cases been slightly altered in the Subject Index, hence, when original titles are required, reference should be made in the Author Index. It is obvious that great care has been exercised in compiling this publication, and it will undoubtedly prove very useful.

We have received the annual report of the Calcutta School of Tropical Medicine, Institute of Hygiene, and the Carmichael Hospital for Tropical Diseases for 1926. A history of the School is given, together with a summary of the past year's work and of the research work carried out, with a portrait of its founder, Sir Leonard Rogers.

THE British Drug Houses, Ltd., Graham Street, City Road, N.1, issues a useful booklet on the use of stams in bacteriology and pathology, with their formulæ, and a price list of standard microscopic stams. For those who only occasionally employ stams, small quantities of the solutions are supplied.

WE have received from Messrs. Baird and Tatlock, Ltd. (14-15 Cross St., Hatton Garden, E.C.1), vol. 3 of their "Standard Catalogue of Scientific Apparatus" (1927). This deals with the biological sciences, excluding physiology, to which vol. 2 is devoted. It contains a very full list of apparatus for teaching and research required in anatomy and microscopy, botany and zoology, bacteriology, pathology and hygiene, and

agricultural science. In addition to making apparatus in their own workshops at Walthamstow (of which several excellent plates are inserted), the firm also acts as agent for many individual makers of scientific instruments, e.g. microscopes and inicrotomes. The catalogue is extraordinarily complete, and an almost bewildering range of apparatus is listed. It is profusely illustrated, and being printed on paper with a good surface, the illustrations are very clear and distinct. Messrs. Baird and Tatlock also design and supply laboratory furniture and equipment.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned .—A registrar of the Wigan and District Mining and Technical College-The Principal, Wigan and District Mining and Technical College, Wigan (July 11) An assistant lecturer in botany at the University College of North Wales, Bangor-The Secretary and Registrar, University College of North Wales, Bangor (July 12). Junior assistants at the National Physical Laboratory for work in connexion with photometry and metallurgy -The Director, National Physical Laboratory, Teddington (July 16) An instructor for carpentry and joinery and building construction in the School of Building, Willesden-The Principal, Willesden Polytechnic, Priory Park Road, Kilburn, NW.6 (July 16). A lecturer in biology in the Edinburgh and East of Scotland College of Agriculture—The Secretary, Edinburgh and East of Scotland College of Agriculture, 13 George Square, Edinburgh (July 18). A fulltime lecturer in the Department of Mechanical and Civil Engineering of Loughborough College—The Registrar, The College, Loughborough (July 18). A demonstrator in geology in the Queen's University of Belfast-The Secretary, Queen's University, Belfast (July 20). A lecturer in zoology at Armstrong College, Newcastle-upon-Tyne--The Registrar, Armstrong College, Newcastle-upon-Tyne (July 23). A senior lecturer in the Department of Electrical Engineering of Loughborough College-The Registrar, The College, Loughborough (July 23). A reader in organic chemistry in the University of Dacca, India-The Registrar, University of Dacca, East Bengal (July 30). A university lecturer in structural crystallography in the University of Cambridge-Prof. A. Hutchinson, Pembroke Lodge, Cambridge (July 31). A professor of chemistry in the University of Adelaide -The Registrar, The University, Adelaide, South Australia (August 15), or the Agent-General for South Australia, Australia House, 112 Strand, W.C.2 (October 1). A test assistant in the Metallurgical Department of the Royal Aircraft Establishment - The Chief Superintendent, R.A.E., South Farnborough, Hants (quoting A.193). A visiting lecturer in structural engineering, drawing, and graphics at the Borough Polytechnic Institute-The Principal, Borough Polytechnic Institute, Borough Road, S.E 1. A woman clinical pathologist at the Lady Hardinge Medical College, New Delhi, India-Dr. Kate Platt. 59 Queen Anne Street, W.1. A professor of medicine in the University of Edinburgh—The Secretary to the Curators, 4 Albyn Place, Edinburgh.

#### Research Items.

A Jaina Image of Ajitanâtha —In the Indian Antiquary for April, N. C. Mehta figures and describes a beautiful image of Ajitanâtha, according to tradition, a contemporary and cousin of the mythical prince Sagara. It was executed in A D. 1053, when Jamism, having suffered an eclipse in the south after the sixth century A.D., was approaching its climax in western India under the Solanki rulers of Gujarat. The image is 51 inches, or, with the pedestal, 63 inches in height. Judging from the exceptionally bright and yellow lustre of the body, the metal must contain a large amount of gold. It stands in the characteristic pose of a Jaina kevali, i.e. "one who has attained the Peace born of perfect knowledge and of absence of attachment to things mundane." The face is that of a young man, strikingly handsome, and the limbs are beautifully modelled and of pleasing proportions. The loin cloth is attached to an elaborately carved girdle of fine design. The ushnîsha, the symbol of enlightenment, is just indicated, while the Jewel of Illumination is prominently shown on the forehead. An inscription states that this statue was set up in memory of the saint Shâlıbhadra by his pupil Pûrnabhadra. The statue is still worshipped in the Ajitanâtha Temple in Zaverivâdâ at Ahmadâbâd. It is a very favourable example of the art of casting metallic images which reached a high standard in medieval Gujarat, and of which a large number of good specimens are still to be found in the Jama temples scattered throughout Gujarat and Rajputana.

Food and Habits of Meganyctiphanes.—An account is given by Mr. R. Macdonald (Jour. Marine Biol. Assoc., vol. 14, No. 3, March 1927, pp. 753-84) of work carried out in the Clyde area from the Marine Biological Station at Millport on the biology of this euphausiid, which is of great importance in the economy of certain fish, particularly hake and herring. He finds it to be a suspension feeder, subsisting on minute organisms and detritus. Vegetable detritus of land or coastal origin appears to be of special importance as a source of food in the area studied. Evidence is given of partial diurnal migration in a vertical direction, but further work seems to be required to establish the conditions of such movements. In the second paper, Mr. Macdonald describes certain irregularities in the larval development of M norvegica (vibid. pp. 785-94).

A FLAGELLATE IN A NEMATODE.—Dr. T. Goodey and Miss M. J. Triffitt (*Protozoology*, No. 3, 1927) describe observations on flagellates in the intestme of the nematode Diplogaster longicauda. This worm was living in numbers among decayed material from a narcissus bulb, and many of the worms harboured the flagellates in their intestine—in some cases the gut "was literally packed with them." The flagellates are  $10\mu$  to  $12\mu$  long, fusiform in shape, and have a single flagellum. Occasionally the flagellates issued from the anus of the worm into the fluid—material from the decayed bulb plus a little tap-water—and in some of them a contractile vacuole was seen to make its appearance towards the anterior end of the body, but a contractile vacuole was not seen in any of the flagellates still in the gut of the worm. The nucleus of the flagellate is of the vesicular type with large karyosome, the parabasal body is rod-shaped or oval, and there is a small anterior centrosome from which the axoneme takes origin. The free part of the flagellum is  $8\mu$  to  $12\mu$  long. Both leptomonad and crithidial forms were observed and division stages of both forms were seen. A Leishmania stage was not

met with. The flagellates agree with *Leptomonas* butschlin in general shape and size, but the authors prefer to leave open the question of the name of the organism.

GROWTH OF THE SKELETON IN TWO ECHINOIDS -Although much valuable research has been conducted on the embryology of sea-urchins, few workers have investigated the development of the skeletal plates from the embryo to the adult, and indeed the difficulty of rearing the forms in an aquarium has been a sufficient hindrance to any complete study. Fortunately, modern methods have at last enabled Prof. MacBride and his pupil Dr Isabella Gordon to obtain excellent series of a regular urchin, Echinus miliaris, and an irregular heart-urchin, Echinocardium cordatium, and very thorough and complete accounts of the development of the test have been published by Dr. Gordon (*Phil. Trans. Roy Soc*, B, vols. 214 and 215). Both memoirs contain valuable additions to our knowledge, but the latter lends itself better to summary here. While the adult heart-urchin has the outline which its name implies, with the apical system from which radiate five petal-shaped ambulacra, on the upper surface, with the mouth shifted to the front of the under surface, and with the anus at the other end of the body, the young as it emerges from the larval stage has an almost circular outline, with the mouth central on the under surface, and the anus enclosed by the central apical system, from which radiate ambulacra of primitive structure. Dr. Gordon traces in minute detail the shifting of mouth and anus and the gradual growth and specialisation of the ambulacra. For her statement of facts we have nothing but praise, but when she says that "the migration of the anus within the periproct is due to a difference in the rate of growth of the various plates, or that the periproct is encircled by the inter-ambulacrum "as a result of" the addition of inter-ambulacral plates, then we suggest that the alleged cause is merely a concurrent phenomenon. If anything, it is the tension on the gut as the body elongates that pulls down the anus; and the plate-building follows this.

SEISMOGRAPH RECORDS.—In the Issue of the Proceedings of the Imperial Academy of Japan for March, Mr. K. Suyehiro directs attention to the possibility of a seismograph installed so as to be sensitive to earth movements in a particular direction being set in motion by disturbances at right angles to those it is intended to record. He shows that an instrument set up, for example, to record movements in the north-south direction may be set in motion by an east-west movement of half the natural period of the instrument, and that the records of such an instrument are liable to misinterpretation on this account. The possibility of the motion of the instru-ment to which attention is thus directed, will be recognised by those who are acquainted with Melde's experiment, in which a stretched wire is set into transverse oscillation by one end of it being attached to the prong of a tuning-fork vibrating along the axis of the wire.

GEOPHYSICS IN FRANCE.—The Institut de Physique du Globe de l'Université de Paris, with which is associated the Bureau Central de Magnétisme Terrestre, under the directorship of M. Maurain, has recently published vol. 4 of its *Annales*. It gives an interesting and valuable record of the considerable activity which now exists in France in the investigation of

terrestrial magnetism and other branches of geophysics. It contains nineteen articles, of which the first and longest is the report of the Val Joyeux magnetic observatory, including tables of hourly values of the three elements, for 1924. A shorter report of the less comprehensive observations at Nantes is also given. The remaining articles on magnetism mainly refer to survey measurements in various parts of France, and also in Syria. Other sections deal with meteorology, seismology, and actinometry at Parc Saint-Maur, and with atmospheric electricity observations made on board the ship Pourquoi-Pas? in the Arctic region.

The Height of Iridescent Clouds.—In Geophysical Publication No. 2 of Volume 5, published by the Norwegian Academy of Science, Oslo, Prof. Carl Stormer gives the results of his measurements of the heights of iridescent or mother-of-pearl clouds. His method is to take simultaneous photographs of the clouds from two distant stations at a time when some of the brighter stars will show on the plates. The altitude of the cloud can then be calculated from its parallax. From observations taken at stations 26 kilometres apart during the evening of Dec. 30, 1926, he finds the altitude to be 27 kilometres.

CAUSES OF TROPICAL RAINFALL —The rainfall of the Sudan, both west and east, has been found to fluctuate considerably from year to year, not in-frequently to such an extent that deficiency or irregularity leads to famine. In discussing the causes for this in a paper in Matériaux pour l'étude des calamités (No. 11, 1926), Mr. G. T. Renner maintained that all tropical rainfall is really monsoonal in character During the period of high sun, the land masses are centres of low pressure surrounded on sea and land by areas of higher pressure. Monsoonal currents blowing from the sea into these areas of low pressure bring heavy rainfall. The alternate cooling of the tropical lands, when the sun is low, leads to a high pressure and a dry season. The double rainy season of equatorial regions is caused by those areas being crossed by both sets of monsoonal currents. variations in the rainfall of the Sudan are due to variations in the intensity of the low pressure and the resultant strength of the monsoon currents. Variation in solar weather must cause the variation in the intensity of the low pressure. Mr. Renner further points out that while all tropical rainfall is liable to vary from year to year, it is only in the savanna and grassland regions, where normal rainfall makes agriculture just possible, that a marked deficiency leads to famine conditions. He thus considers that all the tropical savannas and grasslands are potential famine areas.

The Sensitive Centres of Silver Bromide Particles.—It is well established that in the development of an exposed gelatino-bromide plate the reduction of the silver salt to metal (the blackening), starts at 'centres' or points on the crystals or particles of the silver salt. It is generally assumed that these points where the action begins are more sensitive than the rest of the crystal or particle Dr. S. E. Sheppard has found that this sensitiveness is caused by certain sulphur-containing organic bodies present in the gelatin, and considers that the extra sensitive points are invisibly small specks of silver sulphide. The existence of these centres or starting-points of action has been demonstrated by stopping development at a very early stage, before the reduction has had time to extend to the whole particle. Messrs. Sheppard, Trivelli, and Wightman now find (Journal of the Royal Photographic Society, June 1927) that the

existence of these centres may be shown also by 'printing-out,' that is, merely prolonging the exposure by subjecting the plate to the action of an intense beam of white light for four minutes. They find, too, that by soaking a plate for one hour in a very dilute solution of allylthiourea and then for five minutes in a 1 per cent. solution of sodium carbonate, a number of black specks appear that were not there before. They "feel safe in saying" that these black specks are formed by the transformation of invisible specks of allylthiourea-silver bromide into silver sulphide. The communication is illustrated with excellent photographs which clearly show the results stated

PHOTOCHEMICAL EQUILIBRIUM IN NITROGEN PER-OXIDE.—In the course of some photochemical investigations, R. G. W. Norrish noticed that nitrogen peroxide enclosed in a water-jacketed vessel and illuminated by the rays from a quartz mercury vapour lamp showed a considerable increase of pressure, which was too great to be attributed to the heating effect of the absorbed light. The experiments which have been carried out in order to determine the cause of this pressure change are described in the April issue of the Journal of the Chemical Society. It has been found that the establishment of a photochemical equilibrium between nitrogen peroxide and nitric oxide and oxygen is the chief cause of the increase of pressure. To this must be added the direct heating effect of the absorbed radiation, and the effect of the heat liberated from the reverse reaction  $2NO + O_2 \rightarrow$ 2NO<sub>2</sub>. A reaction mechanism is suggested which is capable of giving results in quantitative agreement with those determined experimentally.

The Celorides of Sulphur.—Although the evidence as to the exact nature of the chlorination products of sulphur is somewhat contradictory, it is generally agreed that a monochloride and a tetrachloride exist, and that the so-called 'dichloride' is merely a mixture of these two. This conclusion is largely based on cryoscopic experiments, and in the Journal of the Chemical Society for April, Lowry, M'Hatton, and Jones describe the results of a careful redetermination of the freezing-point curve of the chlorides of sulphur over the range from 16-70 per cent. of sulphur. This re-determination has revealed, in addition to the main sections corresponding to the separation of the monochloride and the tetrachloride, two well-defined breaks which are attributed to the crystallisation of the dichloride and of a trisulphur tetrachloride of the formula S<sub>3</sub>Cl<sub>4</sub> which has not been prepared before. It is proposed to discuss the molecular structure of these compounds in a later paper.

COKING PROPERTIES OF COAL.—One branch of the work of the Fuel Research Division is the physical and chemical survey of British coal seams. Dr. J. T. Burdekin, of the South Yorkshire Survey Staff, has published an investigation of the caking power of coal (Fuel Research Survey, Paper No. 8. London: H.M. Stationery Office. 1s net). Numerous attempts have been made to give a quantitative figure to the tendency of a coal to produce a coke on carbonisation. So many factors operate that a single simple test is difficult to find. The author has carbonised different mixtures of the coal with calcined anthracite at defined and various rates of heating, and determined the crushing strength of the product in a special machine. The results are displayed as 'caking power curves' (crushing strength against composition of coalanthracite mixture), and it is believed that these curves can be interpreted as giving a measure of the capacity of a fuel to give a satisfactory coal in an oven.

. . . .

## The Expedition of the Meteor in the South Atlantic.

THE third report 1 on the progress of the Meteor Expedition, of which an account was given in NATURE of Jan. 1. includes some interesting results of an extensive survey of the chemical and physical conditions of the waters of the South Atlantic.

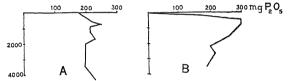

Water cooled below the Arctic ice in the northern hemisphere falls and creeps slowly southward as a deep current, rising in the zone 50°-60° S. and turning back to flow as an intermediate current at a depth of between 500 metres and 1000 metres towards the equatorial zone, where it mingles with the upper layers A similar type of circulation was recently found in the Indian Ocean by Schott 2

The estimations of dissolved phosphate made on

this expedition are singularly interesting as a factor governing the fertility of the ocean, for the conclusions based on them by Wattenberg are in excellent agreement with the conclusions arrived at by Atkins<sup>3</sup> from

Mean latitude	55° S	48° S	42° S	35° S	28° S	23° S	15° S	10° S	3° S	2° N.

his work in the North Atlantic and around the coasts of Britam. In the tropics the sudden increase of phosphate with depth is accounted for by its utilisation in the surface layers by vegetable plankton

1—Vertical distribution of dissolved phosphate in the South Atlantic Abscissæ show milligrams  $P_2O_5$  per cubic metre, ordinates depth in metres  $A:\ ca\ 50^\circ\, S.$ , B. Tropics. Fig. 1

organisms; here the sudden difference in density between the light warm upper layers and the cold heavy water below hinders mixing by means of convection currents, whereas in more southerly latitudes the upper layers, nearer in density to the water below, are continually being renewed by this means, giving rise to much greater plant growth.

<sup>2</sup> Ann der Hydrog, 54, 417-431, 1926

<sup>3</sup> Jour Marine Biol Assn., 13, 119-150, 700-720, 14, 447, 1923-1926

NATURE, 116, 784, 1926

On the West African coast, water rising from the depths continually enriches the surface layers and occasions a rich growth of plankton A considerable fouling of the ship's bottom in this area was also noticed, and it was observed that the colour of the sea was modified by the greater number of plankton organisms in it, which by reflecting yellow and green light give it a greenish blue appearance on looking down over the ship's side

A table by Hentschel shows the average number of indıvıdual plankton organisms per litre found during the course of the ten cruises already made across the ocean, and brings out very clearly the relation of fertility of the water to latitude

The minimum of life does not occur in the equatorial region but around latitude 28° S., in the region corresponding to the Sargasso Sea in the North Atlantic, where warm surface water forms a pool in the ocean.

In this connexion it is interesting that Lohmann 4 m the Deutschland found more plankton in the equatorial region than in about 20° N. The explanation in both cases seems to be that water rich in phosphate and nitrates rises near the equator to take the place of that which flows away in the westgoing currents, whereas immediately north and south of this zone the upper layers are not enriched from below to any appreciable extent and plant life is reduced to a minimum, giving rise to the barren deep blue areas of the oceans.

Estimations of alkalinity of the water in the tropical regions indicated that the surface layers were to a slight extent depleted of dissolved calcium carbonate through the agency of minute plant organisms which secrete an enveloping shield of calcareous plates, while the water close to the bottom was somewhat richer than the intermediate layers owing to solution of calcium carbonate from the detritus of dead organisms. Sea water generally is almost, but not quite, saturated with respect to calcium carbonate.

4 Arch. fur Biontologie, 4, Heft 3. Berlin, 1920.

## The Gas Industry and Carbonisation.

TINDER the presidency of Mr. J. Wilkinson, of Nottingham, the Institution of Gas Engineers held its annual meeting in London on June 14-16. Mr. T. Carmichael discussed the economics of carbonisation as based on operations of the Portsmouth Gas Company, where a wide range of plant is at work. The cost of production of gas in vertical and horizontal retorts showed no great difference and is only half that of the cost of producing carburetted water gas. There is then no incentive to produce gaseous fuel from oil at the present time, so far as cost of production is concerned. Mr. G. M. Gill described types of modern chamber ovens and coke ovens and discussed their suitability as carbonisation units for gas-works purposes. Mr. T. Canning devoted a paper to the relations of a gas undertaking to its con-The pre-carbonisation of coal before combustion is to-day kept constantly in the public eye. The town's gas industry is carrying out such processes under strictly commercial conditions, and is the

only industry doing so on a national scale. Its results and experiences as indicated by these papers deserve close study by all advocates of coal carbonisation.

The progressiveness of the industry is indicated by the great space devoted to the various reports on research. The Gas Research Fellow's report of a study of the properties of coke prosecuted at the University of Leeds contains more observations on the remarkable influence of morganic catalysts on the gasification of coke in steam, carbon dioxide, and oxygen. Sodium carbonate is again shown to have a farreaching effect on these reactions. An interesting experimental technique is described for studying the reactivity of carbon with oxygen which, owing to the great evolution of heat, has been a very difficult matter. In the eighteenth Report of the Joint Research Committee with the University of Leeds, an account is given of studies of the carbonisation process as applied to 30 lb. charges. The rôle of sodium carbonate, which had been demonstrated on

the laboratory scale, has been confirmed on 30-lb charges and a striking increase in the production of gas was shown, doubtless owing to the decomposition of water vapour present by the carbon, stimulated

by the presence of the soda.

The seventeenth Report of the same Commuttee gives a continuation of the study of the products of combustion of gas fires. In order to do this, it was necessary to develop and revise the method of determining carbon monoxide to deal with the minute traces which here require measurement. It was considered possible to do this with a precision of 1 part in a million. It was also established that carbon monoxide is always present in a city atmosphere in quantities reaching 6 parts per million under normal conditions, and in foggy weather reaching 25 parts. In association with the British Refractories Research Association, the Institution of Gas Engineers supports a wide range of experimental work which was reported to the meeting.

## University and Educational Intelligence.

BIRMINGHAM.—The Charter has been revised so as to embody alterations and additions the desirability of which has been suggested by experience. The chief points are: (1) Alterations in the titles of officers of the University. The "Vice-Chancellor" becomes "Pro-Chancellor," and the "Pro-Vice-Chancellor" becomes "Deputy Pro-Chancellor." The "Principal" becomes "Vice-Chancellor and Principal" and the conferring of degrees will be one of his functions. (2) The appointment of the Vice-Chancellor and Principal is to be made by the Court of Governors, on the recommendation of the Council, who shall have consulted the Senate. The appointment was formerly made by the Crown (3) The Guild of Graduates will elect a representative on the Council, and the non-professorial staff will elect from its number one member of Council and six representatives on the Court of Governors. (4) Power has been granted to create a Faculty of Law. The revised ('harter has been approved by the King in Council.

OXFORD.—The Board of the Faculty of Physical Sciences has appointed Mr. Bertram Lambert, follow of Merton College, to be Aldrichian demonstrator in chemistry for four years from the first day of Michaelmas term, 1927.

St. Andrews.—At the graduation ceremonial on June 28, the honorary degree of LL.D. was conferred (in absentia) upon Prof. John Rankine Brown, of Victoria College, Wellington, New Zealand. The degree of D.Sc. was conferred upon W. S. Duke Elder for a thesis on "The Nature of the Intraocular Fluids and the Pressure Equilibrium in the Eye," and on David Stiven for a thesis entitled "A Study of the Phosphatese-Phosphatase System of Muscle Extract."

THE University of Maryland has conferred the honorary degree of Doctor of Science on Sir John Russell, Director of the Rothamsted Experimental Station.

THE degree of Doctor of Science has been conferred by Columbia University, New York, on Frank B. Jewett, vice-president of the American Telephone and Telegraph Company, and president of Bell Telephone Laboratories, New York. In conferring the degree, President Butler referred to Dr. Jewett as "bringing to the art of telephony and its development the full weight and power of modern scientific knowledge; building on this foundation a notable organisation of

research workers and applied scientists, and thereby contributing in highest degree to the perfection of the art of communication between human beings and over increasing distances."

In a letter in the Times Educational Supplemen for May 28, the chairman of a special committee of the Science Masters' Association directs attention to the strange diversity in the attitude taken up by different universities with regard to the recognition of advanced courses in science in secondary schools. While exact uniformity may not be essential, there seems to be a danger that the progress of scientific education may be hampered in certain areas owing to the policy of the local university; Oxford and Cambridge show their appreciation of the advanced courses by granting certain excimptions to students who have passed the higher certificate, and their influence, fortunately, is not confined to any particular locality. The last year at school is often of supreme importance in the formation of the mild and character of a boy; if injudicious pressure is brought to bear upon him to leave school and enter on a career of narrow specialisation at too early an age, the boy himself may never attain to his full mental stature, the university will receive less competent students, the standard of science teaching for all boys in the school will be depressed and the status of science relative to other subjects will mevitably suffer.

THE increase in recent years in the demand for higher education and in its cost is shown in a recent publication by Mr. A. J. Klein, Chief of the Division of Higher Education, Bureau of Education of the United States ("Higher Education Biennial Survey, 1922-1924" (Bulletin, 1926, No. 20); Washington, D.C.: Government Printing Office). For example, in 1912 there were 255,673 students enrolled in the colleges and universities of the United States, in 1922 the number had become 550,906. The meome of higher institutions in 1912, excluding additions for endowment, was 90 million dollars; by 1922 if had risen to 273 million. This increase is far greater than the increase in population or in the income of the country. The additional money has been largely used in increasing teachers' salaries. In small colleges salaries have risen from an average of about 1400 dollars to an average of 2000; in medium-sized institutions from 2500 dollars to 4000; in large institutions from 5000 dollars to 8000 or 10,000. The number of members of staff increased from 30,000 in 1912 to 50,000 in 1922. There has been much criticism of the products of higher education. There is a general demand that those who enjoy its benefits should contribute more largely to its cost. Everywhere there has been a tendency to increase tuition and institutional fees, but this has had little effect in reducing the number of students. measures have been adopted with the view of restricting admission to those who are most likely to benefit from a university training; e.g. Harvard has limited its entering class to 1000 and changed its entrance requirements; while the personal interview has also been used. The junior-senior high-school system is being modified with the view of providing completion courses for those who are not proceeding to college. "The burden upon the [university] institutions makes them friendly towards the idea of developing separate two-year junior colleges," which will (1) provide a liberal arts course leading to entrance to the 'junior year' in a university, i.e. skipping the freshman and sophomore years; (2) conduct two-year professional or pre-professional courses; (3) offer twoyear completion courses for those who do not desire to secure a degree or enter a profession.

## Calendar of Discovery and Invention.

July 10, 1817.—For his important discoveries on the polarisation of light, Brewster in 1815 received the Copley Medal. In his investigations he was led to the invention of the simple scientific apparatus, the kaleidoscope, which he patented on July 10, 1817. As a toy the kaleidoscope quickly gained immense popularity in England and America. Writing from London in May 1818, Brewster said, "You can form no conception of the effect which the instrument excited in London. . . . Infants are seen carrying them in their hands, the coachmen on their boxes are busy using them, and thousands of poor people make their bread by making and selling them"

July II, 1861.—Kirchhoff's great paper "On the Solar Spectrum," containing his views of the true nature and the chemical constitution of the sun from his interpretation of the Fraunhofer lines, was read before the Berlin Academy of Sciences on July 11, 1861. To no one did Kirchhoff's work appeal more than to Huggins, who years afterwards wrote: "This news was to me like the coming upon a spring of water in a dry and thirsty land. Here at last presented itself the very order of work for which in an indefinite way I was looking—namely, to extend his novel methods of research upon the sun, to the other heavenly bodies."

July 12, 1770.—The spinning jenny constructed by Hargreaves and patented by him on July 12, 1770—an epoch-making invention—has been described as "the instrument by which (so far as we have any authentic and trustworthy evidence) the human individual was first enabled, for any permanently advantageous and profitable purpose to spin wool, cotton, or flax into a plurality of threads at the same time and by one operation."

July 12, 1771.—On this day H.M.S. Endeavour anchored in the Downs, after her three years' voyage round the world under the command of James Cook. In 1769, observations of the transit of Venus had been made, and this was followed by the circumnavigation of New Zealand and the survey of the Great Barrier Reef of Australia.

July 12, 1796.—In a letter to Sir Joseph Banks, dated July 12, 1796, Rumford offered £1000 to the Royal Society "to the end that the interest of the same may be by them and by their successors, received from time to time for ever," and the amount applied every second year as a premium to the author of the most important discovery which shall be published in any part of Europe during the preceding two years, on heat or on light.

July 13, 1897.—After his demonstrations in Bologna in 1895 and in England in 1896, Marconi, at the invitation of the Italian government, made experiments at Spezia, where, on July 13, 1897, radio messages were sent between a land station and Italian warships over a distance of 12 miles.

July 15, 1662.—The beginning of the "Royal Society of London for Improving Natural Knowledge" dates from July 15, 1662, when the first charter passed the Great Seal. Weld in his history says: "The first Charter is on four sheets of Vellum; it was drawn by Sir Robert Sawyer, then Attorney-General, and is remarkable for its cleamess and legal terseness; the first sheet contains some remarkably handsome ornamental capitals and flowers, with a finely executed Portrait of Charles II. in Indian Ink with the initial letter C. The Great Seal of the Kingdom in green wax is appended to the Charter."

#### Societies and Academies.

LONDON.

Royal Society, June 30.—A. V. Hill, K. Furusawa, and J. L. Parkinson. The dynamics of 'sprint' running. By an application of the theory of dimensions it is shown that the speed of an animal, such as man, is limited by the inertial stresses to which the structures are subjected during movement. The 'viscosity' of the muscles is the chief factor. For experimental work it is necessary to employ maximal contractions. The case of submaximal contractions is theoretically discussed. A runner exerting maximal effort propels himself with constant force. The 'constants' of a given runner can be determined with very fair accuracy, and the work done, in running, against viscosity and resistance of the muscles can also be determined.

A. V. Hill, K. Furusawa, and J. L. Parkinson: The energy used in 'sprint' running. The mechanical work done against the viscous resistance of the muscles of the runner has been compared with the amount of oxygen used in recovering from the effort. The result shows a 'mechanical efficiency' of about 38 per cent. In a man running 200 yards, at top speed throughout, fatigue begins to appear after 70 yards, and by the end the speed has fallen by about 12 per cent. This fatigue is due to the enormous rate of expenditure of energy in running at top speed; one subject, who ran his first 100 yards in 9.88 sec., and his second in 9.57 sec, developing 8½ horse-power at his maximum velocity (11.46 yards per sec.) and liberating 4 gm. of lactic acid per sec. in his

R. G. Canti and F. G. Spear: The effect of gamma irradiation on cell division in tissue culture in vitro. The extent of inhibition of mitosis was determined by making counts of the total number of cells undergoing mitosis and expressing these counts as percentages of the total number of cells undergoing mitosis in the same number of unirradiated cultures of the same batch used as controls For a given intensity of irradiation, there is a period of time of exposure which must be exceeded before any change in the number of cells undergoing mitosis is observed, and after this minimum time is passed the effect upon mitosis is sudden and well marked. Under the conditions of experiment, a longer time is required to bring about this biological effect with weaker intensities than would be expected from the physical determinations, and there is a minimum intensity of irradiation below which no such effect takes place.

A. N. Richards and J. B. Barnwell: Experiments concerning the question of secretion of phenosulphonephthaleme by the renal tubule. Phenol red applied to the surface of a decapsulated rabbit's or frog's kidney passes into the urine eliminated by it. When salt solution is made to flow from the ureter through the tubule to the capsule of Bowman, during perfusion of the renal portal system with phenol red solution, phenol red can be identified in the saline collected from the capsule. Complete obstruction of the circulation through the glomerulus does not prevent phenol red from entering the tubule and becoming concentrated there. When an excised frog's kidney is immersed in oxygenated phenol red solution, the dye passes into the tubule and becomes concentrated. These facts, which present the appearance of secretion of phenol red by tubule cells, are best explained by assuming diffusion of water and dye into the tubule at one level, active extrusion of water and retention of dye at another, and a fluid current within the tubule from one level to the other.

S. B. Schryver and H. W. Buston The isolation of some undescribed products of hydrolysis of proteins (Part iv.). When gelatin is hydrolysed rapidly with sulphuric acid, it yields about 20 per cent. of its introgen in the form of diamino-acids; if, however, the gelatin is allowed to stand with acid in the cold for a day before hydrolysis, the diamino-acid content is increased to about 29 per cent. This increase is due mainly to the formation of dl-lysine; at the same time there is a slight increase in the amounts of arginine and active lysine. The dl-lysine is not formed by mere racemisation of active lysine, but must be formed from some precursor which only yields the base by the action of cold acids.

J. B. Cohen, with others. The therapeutic action

J. B. Cohen, with others. The therapeutic action of some bismuthyl derivatives of organic hydroxyacids. The therapeutic action of several of these substances on Spirochæta Laverani has been investigated. The action depends not only on the bismuth content, but also on the chemical constitution of the product under investigation, so far as the effect on mice infected with Sp. Laverani was concerned. The effect of bismuthyl saccharic acid and its sodium salt has been tried in human subjects, but these substances possess no great advantage over the bismuth preparations in general use. The main fact emerging from a chemical study of the bismuthyl series is the greater reactivity of esters over the corresponding

hydroxy-acids.

T. S. P. Strangeways and Honor B. Fell: A study of the direct and indirect action of X-rays upon the tissues of the embryonic fowl. The destructive effect of a given dose of X-rays upon the tissues of an embryo is correlated with the age of the embryo irradiated. With the exception of a relatively small number of cells destroyed by the direct action of radiation, the death of the tissues in 6-day embryos is due to an indirect action. There is no evidence that the cells qua cells of a 6-day embryo are more susceptible to the action of X-rays than those of a 20-25-hour embryo. The degenerative changes induced in the tissues of 6-day embryos by X-rays are intimately related to cell metabolism, since they are inhibited or greatly retarded when metabolism is arrested by low temperatures. The lethal action of X-rays is not due to the formation of stable toxic products

C. M. Yonge: Structure and function of the organs of feeding and digestion in the septibranchs, Cuspidaria and Poromya. The septibranchs are carmivorous and specialised for taking in and digesting large food particles, which, with water, are drawn in by the action of the septum, a highly muscular organ, striated in Cuspidaria, but not in Poromya. passes from the infra-septal cavity into the supraseptal by way of fine pores in Cuspidaria, and by two pairs of branchial sieves in Poromya. Labial palps are small, ciliated on inner side, muscular; they push food into the mouth. All clia in infra-septal cavity carry particles away from mouth, either into supraseptal cavity or to posterior end of infra-septal. The œsophagus is wide and muscular, stomach long and cylindrical, lined throughout with thick cuticle, muscular and free from surrounding tissues; it acts as a gizzard. The digestive diverticula have unusually short and wide ducts and the tubules provide the only absorptive surface in the gut All modifica-

tions of gut appear correlated with the type of food.

B. K. Das: The bionomics of certain air-breathing fishes of India, together with an account of the development of their air-breathing organs. The post-larval development of the air-breathing organs in six genera of air-breathing fresh-water fishes, namely, Claries, Saccobranchus, Anabas, Ophio-

cephalus and Amphipnous, is described. In Anabas and Macropodus the organ consists of an air-chamber, or secondary lung, situated on either side of posterior region of head, each of which lodges three vascular shelly labyrinthiform plates; in Clarias there are two vascular tree-like structures made the air-chamber; Saccobranchus has a long tubular lung-like structure extending back from the gill chamber to the sides of body; Ophiocephalus has a vascular air-chamber situated on each side of head, whereas in Amphipnous there are two large 'bladders' resombling amphibian lungs and extending to a short distance behind the head.

(To be continued.)

Royal Anthropological Institute, June 14.—Sir Baldwin Spencer. Recent researches amongst the Arunta with special reference to the Alchera and Churinga beliefs. The chief features of the earlier work of the late F. J. Gillen and the author were (1) the demonstration of the fundamental importance of group relationship in regard to social organisation of the tribes, the existence of which in Australia had first been shown by Howitt and Fison, (2) the complex development of the totemic system and of the customs and beliefs associated with this; and (3) the existence of a theory of conception related to a belief in an ancestral spirit individual who voluntarily and without any necessary relation to natural processes reappeared in successive incarnations. The Rev. C. Strehlow, in charge of a Mission Station amongst the Arunta, has arrived at conclusions in regard to the significance of the Churinga and, more especially, of the Alchera belief, which are different from these. Recent inquiries have confirmed Spenser and Gillen's original account, so far as it went. The term Alchera is of somewhat vague and wide import. It is associated in the native mind with the far past times in which his ancestors came into existence, lived and died. Every individual has his, or her, Alchera. Its use by missionaries as the equivalent of god is wrong and misleading. The Churinga belief, according to which the spirit part of every individual is associated with one of these sacred slabs of stone or wood, is fundamentally as Sponsor and Gillen described it. A great leader, Numbakulla, who appears in various forms in tradition, originally made everything. The original Churinga were split into two, with one of which a male and with the other a female spirit became associated. When the Alchera ancestor died his spirit part also split into two, one forming an everlasting Arumburinga, the other a Kuruna that continually undergoes re-incarnation.

## MANCHESTER.

Literary and Philosophical Society, May 10.—A. Lapworth and E. N. Mottram: A survey of direct and collateral evidence bearing on some stereochemical inversions and cross-saturation processes. Bedo's view (Compt. rend., 183, 750, 1926) that the oxygen atom in cyclohexeneoxide lies in the plane of the cyclohexane ring is not accepted. The theory which appears to be most nearly consistent with collateral evidence is that in each of the three steps: (1) cyclohexene to cyclohexene - halogenhydrin, (2) -halogenhydrin to cyclohexene - halogenhydrin, (2) -halogenhydrin to coxide, and (3) -oxide to -glycol involves a 'cross-reaction,' this term being used to include both 'simple stereochemical inversions' (such as, for example, the Walden inversion) and trans- or cross-addition processes. Oxidation of ethylenic compounds by means of permanganate is known to lead, in effect, to cisaddition of 2OH groups, whilst oxidation by hydrogen and other peroxides similarly leads to trans- or cross-addition. The authors criticise theoretical treatment

of the subject by Hilditch (Trans. Chem Soc., 129, 1830; 1926 et seq.), and by Boesekin and Belinfante (Rec des Travaux Chimques, 45, 917, 1926), as the glycols obtained from an ethylenic compound by cis- or trans-addition are, so far as is known, equally closely related to the original compound: they agree, however, with the authors last named in holding that, contrary to the views of Hilditch (loc cit.), there is no evidence of any inversion when permanganate is used, but that a stereochemical inversion probably does occur at the breakdown of ethyleneoxides formed as intermediate products when peroxide is used

#### Paris

Academy of Sciences, May 30 -Ch Barrois, Paul Bertrand, and Pierre Pruvost The coal measures of The principal result of the palaeoutological study of this field is the exact connexion of the veins opened up at Anzın with those of the western end of the Pas-de-Calais, on one part, and with those of Bormage, Limbourg, and the Ruhr on the other part. Moreover, for the first time, the thickness of the Westphalian series at the Belgian frontier can now be fixed.—E L. Bouvier · The Saturnia of Africa -The regulation of governors with André Blondel direct control furnished with dampers.—Léon Guillet: The addition of nitrogen to steels. Measurements of the hardness changes produced in various types of steel by the addition of nitrogen. The effects of various reagents on these steels were also studied .-Ph. Glangeaud. The origin of the fumarole mineral springs of Royat (Puy-de-Dôme).—Jean Effront . The synthesis of proteins by the saccharomycetes. In the course of the anaerobic life of yeast, the part of the sugar which serves for the synthesis of the proteins undergoes a preliminary decomposition without any carbon dioxide being given off and the whole of the carbon in the sugar remains in the yeast produced. If, on the contrary, the solution is strongly aerated, a certain quantity of the sugar is completely burnt and the sugar remaining is transformed into acctaldehyde, which furnishes the carbon for the synthesis of the proteins—Charles Nicolle and Charles Anderson. ## New Aspects of the Nitrogen Problem.

CIR WILLIAM CROOKES'S disturbing pronouncement, made in 1898, on the subject of the approaching failure of the world supply of wheat for lack of combined nitrogen, lives in the memory of many. "Are we to go hungry and to know the trial of scarcity?" he asked, and added, "those present who may attend the meeting of the British Association thirty years hence will judge how far my forecasts are justified." Naturally, a negative answer to his question was given at the British Association meeting last year, but had he said "sixty years hence," no one would have dared to give a confident reply. On the other hand, his prophecy in regard to the manufacture of combined nitrogen has come true. Led by Germany, nearly every civilised country in the world is actively producing synthetic fertilisers. Now, it should be noted that Crookes confined his attention to the need for nitrogen in the production of wheat. Recent events in the agricultural world, however, justify some consideration being given to a wider aspect of the nitrogen problem; for, as a recent writer has said, the sum total of life upon this planet is limited by the amount of available nitrogen in combination; important as wheat is in human dietetics, the supply of meat is equally vital. The farmer everywhere is in fact engaged in the manufacture and marketing of combined nitrogen in one form or another. He buys nitrogen in the form of manures and feeding stuffs, and markets it again as corn, meat, or milk. He makes nitrogen when he sows clover and other leguminous plants; and he conserves it for future use when he lays his land down in grass.

Under ordinary farming conditions in Great Britain, meat and milk are not produced by grass alone. Intensive farming requires that animals shall be fed on concentrates, that is to say, foods rich in nitrogen, and the use of such foods has two advantages: the protein they contain goes in part to make meat or milk, while the portion not digested, as well as that eventually rejected as waste, goes to enrich the soil. It follows that intensive agriculture in the last analysis involves a process whereby foreign nitrogen is brought on to the farm, is converted into products such as corn and meat, again, in part leaves the farm, and in part is added to the soil. We have, therefore, two stages in the exploitation of land for the production of human food, one typical of the apical development of medieval farming, in which the soil of a locality produces the maximum of human food by the united efforts of Nature and the farmer, and the other, typical of farming after the discovery of artificial manures and feeding 'cakes,' in which nitrogen in one or other of two forms is brought on to the farm from outside, subjected, in part, to a conversion process and added to the sum total of home production of food. It may be noted, too, that the purchase of foreign feeding stuffs is merely a transference of nitrogen ' made ' by natural agencies from one portion of the globe to another. In the case of ordinary nitrogenous manures, also, Nature plays a leading part; ammonia salts are waste products of coal consumption: sodium nitrate from Chile is believed to come fundamentally from the excreta of sea-birds, and others, such as blood, bones, etc., are in the same category.

Since the days of Crookes's vaticinations, however, we have entered on a third stage. Agriculture is now drawing on a purely artificial and non-natural source of combined nitrogen, one that makes no call on the resources of the soil elsewhere, or on the natural agencies by which atmospheric nitrogen enters into combination. "The fixation of nitrogen," said Crookes, "is one of great discoveries awaiting the ingenuity of chemists. . . . It is vital to the progress of civilised humanity. . . . Unless we can class it among certainties to come the great Caucasian race will cease to be foremost in the world, and will be squeezed out of existence." The hoped-for discovery has now been made. As a recent writer has said, "It is now the era of nitrogen plenty." The estimated world production of combined nitrogen is now about one and a quarter millions of tons, and it is increasing rapidly year by year. But how does the production of combined nitrogen affect human food? Crookes answered the question so far as wheat is concerned. What about meat and milk? It is obvious that if meat is produced by the feeding of a cereal (such as oats) to animals, an abundance of synthetic nitrogenous fertilisers should cheapen the production of meat. But, as matters stand, the cost of meat is governed by the price of the pasturefed animal plus the cost of purchased foreign foods. In favoured regions in Great Britain it is possible, no doubt, to fatten an ox on home products alone, but in any event the store animal, that is, the animal before it is 'finished' for the butcher with albuminoid and fatty foods, is a product of grass lands. It follows, then, that if we could invariably feed a cow, or finish an ox or sheep on grass alone, we should relieve the farmer of a big item of costthat of cake and corn purchased outside the farm.

We have, then, narrowed the problem to this.

Is it possible by the use of synthetic nitrogenous fertilisers so to improve our pastures that they will be capable of fattening the meat-producing animal? Science has something to say on the subject—and something new. Research on animal nutrition, led by Kellner, the well-known German worker, has been proceeding for more than a generation. Grass in the form of hay has not been overlooked. Its energy value, its starch-equivalent, have been determined: its practical feeding value for maintenance, for production, either alone or in combination with other foods, has been ascertained, but until quite recently its precise value in pasture conditions was unknown.

Scientific knowledge has, however, recently made a great advance. Workers in the Cambridge School of Agriculture have proved that young pasture grass, that is, grass before any lignification of the tissues has set in, is entitled to rank as a concentrated food, both in respect of protein content, digestibility, and starch-equivalent. Its dry matter actually contains so much as 25 per cent. of digestible protein and 75 per cent. of starchequivalent. Further, being the natural food of herbivores, we may assume that its mineral and vitamin contents are properly balanced. So that now a scientific view of the subject warrants the confident statement that if the farmer can supply his milch cows and fattening animals with an abundance of young grass, he can reduce the purchase of extraneous foods. Further, as a means of producing that abundance, he can use synthetic nitrogenous fertilisers; and this is not simply a paper philosophy. During the past two years the theory has been tested in Great Britain on a number of farms (including that at Melchet Court, the property of Sir Alfred Mond), and it has been demonstrated that, provided pasture land is kept closely grazed and that growth is continuously stimulated with nitrogenous and other manures, animals can be kept in healthy productive condition for six months in the year on grass alone. Moreover, and this is important, the number of animals which can be so kept on a specified acreage is greater than that possible by ordinary farming methods.

Of course, productive animals cannot be kept on grass all the year round; at the most they can be so kept for six months in the year, and in any case the practical farming problem presented by the new scheme is far from simple. Under any conditions grass does not grow at a uniform rate during these six months, and consequently a problem of management has to be faced which, for its solution, may necessitate both feeding for limited periods with foreign foods, and the setting

apart of an area of grass land for hay in the standard way. Two further scientific problems also await solution—one, for the plant-breeders, is the making of plants capable of producing a growth of herbage during part of the winter months; the other, for the engineer, is the feasibility of cutting grass in the young condition and preserving it during the winter. A solution on the former lines does not appear to be likely, but the possibility of the second solution is well in sight. The leading producers of synthetic ammonia in Great Britain are actively engaged in exploring the whole problem. (See, for example, "Farm Notes," issued by Messrs. Nitram, Ltd.) They have in operation an extensive series of field trials of which the object is to test the new system of rotational grazing of grass treated with combined nitrogen they are also at the present time making a cake of dried and compressed young grass, and feeding experiments with this substance will be initiated in the coming autumn and winter.

An approach is therefore being made to the complete realisation of Crookes's dream, namely, that the requirements of the country for combined nitrogen shall be satisfied within the country itself—that our imports of that vital requirement shall be reduced to a minimum. Be that as it may, it is satisfactory to know that, as a result of the enterprise of the latest of the great industrial corporations, a further exploitation of the nitrogen problem, as envisaged by a great man of science, is being undertaken.

## Variety and Environment in Lizards.

Der Artenwandel auf Inseln und seine Ursachen, ermittelt durch Vergleich und Versuch an den Eidechsen der dalmatinischen Eilande. Von Paul Kammerer. Nebst einem Anhang: Zur Systematik der adriatischen Insel-Eidechsen, von Otto Wettstein. Pp. xiv + 324 + 8 Tafeln. (Leipzig und Wien: Franz Deuticke, 1926.) 30 gold marks.

MELANCHOLY interest attaches to this paper, the last from Kammerer's pen, which was published only a few months before his tragic death last year. Like his other publications, it is based entirely on work done before the War; for since the War, owing especially to the socialism which became rampant in Vienna, the University of Vienna has become so impoverished that it was unable to pay any but starvation salaries to its staff, and Kammerer left its service and supported himself by journalism and popular lecturing from 1924 until his death.

In 1909 and 1911, and again in 1914, Kammerer No. 3011, Vol. 120]

made a prolonged tour amongst the Adriatic islands, visiting in all fifty of them. The size of the islands varied from tracts of country equal in area to the Isle of Wight to mere islets a few hundred yards across and rocky 'skerries' The object of these excursions was to find out whether distinct races of continental species of animals were to be found on these islands; and if so, how they were related to their nearest allies on the adjacent continent. As he himself says, his purpose was to follow in the footsteps of Darwin and Wallace, and to glean from the study of these island races light on the origin of species.

A preliminary investigation convinced him that the most suitable animals for his purpose were lizards, for these abound in all the islands. Seven species in all were found, namely, two geckos, Tarentola mauretanica and Hemidactylus turcicus, one 'blind-worm,' Ophisaurus apus, and four species of Lacerta, namely, L. major, L. oxycephala, L. serpa, L. flumana. Of these seven species, however, Lacerta major (which is a large form, 18 inches to 2 feet long) and the 'blind-worm' Ophisaurus showed no variations; Tarentola has the habit of clinging to ships and driftwood, and so owes its wide distribution to human agency. Kammerer's attention was therefore concentrated on the remaining four. The gecko Hemidactylus is a nocturnal or at any rate a crepuscular species. and Lacerta oxycephala confines itself almost exclusively to bare rocks. The other two, L. fiumana and L. serpa, are, however, diurnal and frequent herbage and brushwood, and it is they which show marked variations in the different islands, and it is from the study of them that Kammerer obtained the most light on the problem which he sought to solve. These two species, according to Kammerer, are 'good' species. he says that the experienced naturalist never mistakes the one for the other in the field, but that when their diagnostic characters are masked by superimposed 'island' characters they are difficult to distinguish. L. serpa inhabits the whole of the Italian peninsula and L. fiumana the whole of the Balkan peninsula, but the line of division between their territories runs along the Balkan coast, so that several large islands there fall to the share of L. serpa; and, curious to relate, it sometimes happens that an island is occupied by one species and the rocks around it by the other. Kammerer has some speculations as to the geological causes of this irregularity of distribution, but they are outside the scope of the subjects with which this review has to deal.

It should be noted in passing that Boulenger regards these two species as local varieties of Lacerta muralis, and with this opinion the reviewer, after inspecting the types at the British Museum, is inclined to agree; but whether they are considered as true species or varieties is entirely irrelevant to the question at issue. Their territories never overlap: even in the rare cases where they are both found in one of the larger islands, the areas which they respectively inhabit are separated by a 'lizardless' band of country.

Both L. serpa and L. fiumana give rise to wellmarked island varieties, and the most marked of these are found in the smallest islands. In the larger islands it is only possible to find distinctions between island and continental populations by the statistical method: isolated individuals often turn up with peculiarities which become constant and universal in the populations of the smaller These smaller islands, therefore, constitute the crux of the problem, and in endeavouring to account for the production of the strongly marked varieties found in them, Kammerer is approaching the problem of the origin of species from the same viewpoint as did Eimer long before him; for Eimer began his investigations into the causes of evolution by finding and describing a distinct 'variety' or species of lizard on one of the Faraglioni—the rocks in the neighbourhood of the island of Capri in the Bay of Naples.

These varieties differ from the type in colour, size, and shape. The colour of the type is green or greyish-green, with longitudinal rows of dark patches on the back and blue 'ocelli' in various places, such as the armpits and the underside of the throat. The colour below is yellow, sometimes with a reddish tinge, or pale grey. The island varieties can be jet-black, so that markings are not distinguishable from the background; they may be half as long again as the type and broad in proportion, and the tail is marked by a peculiar thickening just beyond its origin.

That isolation is an all-important factor in the production of varieties is clear from the fact that when two populations on the same islet are separated by some barrier which prevents them from intermixing, incipient differences make their appearance. Thus in the islet of Tajan there is a deep valley with perpendicular sides which completely separates the lizards of the eastern half of the island from those of the western half, since no L. serpa will ever climb downwards. The eastern lizards show in the male sex a red coloration on the belly, whilst in the western half both sexes show it.

Granted that isolation is a pre-requisite for the formation of a new variety, it can only act by preventing cross-breeding, and the question remains to be answered—is it chance variation accompanied by natural selection, or is it the direct action of the environment that is the effective cause of the change? Kammerer first examines the case for natural selection. If the black colour is protective, against which foes does it protect? The main enemies of the young lizards are the older lizards. rats, crows, and snakes. But the young in most cases, as on the islets Pomo and Melisello, show considerable traces of the ancestral colouring and only attain full blackness as they grow up, when the first of the enemies is no longer effective. Rats are nocturnal and hunt by scent, and are only found in some islands. Crows only visit islands near the coast, and snakes only occur on a few of the islands. Seagulls never attack lizards, which have, as a matter of fact, established a kind of symbiosis with them, for the lizards haunt the nests of these birds and search the plumage of the nestlings for parasites without molestation; at the end of the nesting season the lizards are plumper and in better condition than at any other time.

On the other hand, Kammerer was able to bring proof that the melanism is due to the direct action of the environment and principally to one factor in it, namely, radiation from rock surfaces. Here he anticipates and answers an objection raised by many naturalists (amongst them Prof. Graham Kerr in his recent book on "Evolution") that only work in the field can detect the causes of evolution, since experimental work, under laboratory conditions, can give no idea of what goes on in Nature. Kammerer replies that field observations can give suggestions as to the causes of evolution. but that the validity of these suggestions must be controlled by experiment. Now Kammerer shows that healthy young Lacerta serpa of typical green colour can be rendered quite dark if exposed for  $1\frac{1}{2}$  to 2 years to strong radiation reflected from stones. If such a pair in middle life are transferred to normal conditions and allowed to breed, they will produce normal green young, but these when they grow up under typical conditions nevertheless repeat a certain portion of the parental darkening. From every island which Kammerer visited, never fewer than twenty and sometimes as many as fifty specimens were sent home to Vienna and there made the subjects of experiments.

The experiment just referred to is only one of a number of which Kammerer gives an account, and they leave no doubt in the mind of the unbiassed reader that Kammerer has fully proved his point. As to the causes of the increased size and the thickened tail, Kammerer freely confesses that he has only surmises; since in the few generations he was able to rear, before the War interrupted his labours, he was unable to analyse their causes by experiment. He thinks that both are cases of over-compensation following respectively on starvation and injury. The black lizards go through seasonal orgies of abundant food, alternating with periods of starvation, and the loss of the tail, owing to mutual quarrels on the islands, is so frequent that the lizards are known to the natives, not as black—that is taken for granted—but as the lizards 'of many tails'

Not only did Kammerer blacken green lizards by exposing them to dryness and radiant heat, but he recalled the black lizards of Melisello to their ancestral green colour by keeping them for two generations in a cool and moist atmosphere He analyses the anatomical bases of the colour There are three pigments—a vellowish-red lipochrome, melanin, and lastly guanin, which produces the blue colour by interference effects. The green is due to the combined effect of the guanin and lipochrome. He shows that as the temperature of the vivarium is increased, first the lipochrome and then the guanin is destroyed, and the melanin extends its range. This state of affairs is reached at 37° C. As the temperature is increased to 39° C., which is the utmost that the lizards can stand, the melanin disappears and a bleached albino results.

The response to radiant heat varies from species to species. L. serpa responds more quickly than L. fiumana. The more a variety is accustomed to heat in its natural habitat, the more slowly it responds to increased heat. The southern populations of L. fiumana are extremely resistant—it looks as if they had acquired an 'immunity' recalling the immunity produced by vaccination

Kammerer of course does not deny the existence of natural selection, but he insists that what is selected is not the random variation in a lucky direction, but the individual that responds best to the environment. Variation, he says, appears at first sight to be random, but when it is looked into closely it is quite orderly and consists of plus and minus variants on a typical mean. There are different systems of organs which he mistakenly compares to the Mendelian genes, which react independently of one another. Thus in some varieties of lizard, blackening is attained by the appearance of melanin in the background; in

others the black patches of the pattern spread until they overwhelm the background. Further, lizards and snakes, like amphibia, have the power of adapting their colour pattern to that of the environment, and this power is exercised through the eye. It is a question of a delicate balance of stimuli whether this power, or the direct response of the skin, shall gain the upper hand. In the islet of Pelagosa, for example, which is covered by a yellowish-green vegetation, L serpa is bright green but the snake Zamenis is represented by an intense melanic variety. The gecko Hemidactylus has a particularly mobile response to its environment by change of colour, recalling in this the well-known chamæleon, yet even here the environment makes an impress on the hereditary constitution, for there is one islet where, owing to the absence of Lacerta, this species has become diurnal, and Kammerer ascertained by keeping this variety alongside of typical specimens in the same vivarium in Vienna that the responses of variety and type to the same environment were different. Kammerer maintains, in fact, that the first step in the formation of a variety is a continual heightened response in the same direction which gradually become engrained in the constitution. "Physiological change precedes morphological change." L. oxycephala, as mentioned above, frequents bare rocks and, unlike L. serpa and L. fiumana, will descend as well as ascend This species has given rise to a black variety on the upper and slopes of the mountains of Herzegovina (L. oxycephala Tomasinii), where the lizards are exposed to pitiless radiation. Thus a variety can originate just as well on the mainland as on an island if intercrossing with neighbouring groups is prevented.

We may in conclusion say a word on the addendum by Dr. Wettstein. This is an admirable systematic review of the Kammerer material. He establishes several new sub-species on the basis of this material, and he mentions the fact which has a direct bearing on the causes which broke Kammerer's heart and drove him to suicide, namely, that a good deal of this material had lost all its colour and was hopelessly macerated and ruined when he came to examine it, by neglect in the museum during and after the War. The reviewer is aware that he speaks for only a small minority of his colleagues, but he predicts that in twenty or thirty years' time, when those fierce partisans whose calumnies were out Kammerer's courage and drove him to his death, have passed away, Kammerer will be ranked alongside Lamarck, Darwin, and Wallace as one of the great architects of evolution.

Really, when one passes from perusing the endless and fruitless pursuits of the elusive gene by the Mendelians, to reading the clear and beautiful arguments of this work, one has the feeling of having passed from the babbling of the nursery to the reasoned debate of the forum

# The Founders of Seismology.

The Founders of Seismology. By Dr Charles Davison. Pp.  $x_{1i} + 240$  (Cambridge . At the University Press, 1927) 12s. 6d. net

THE title of this book at once raises the question of what is a founder For Dr. Davison the answer is simple, he is any one who is no longer living. Yet a different point of view might be adopted, for, if an architectural metaphor is to be used, the history of few branches of knowledge can be divided more readily than seismology into the two periods, of laying the foundations and of building the superstructure. The limit between the two periods lies in the first decade of the present century, and may be more precisely fixed at the time of the Californian earthquake of 1906. Subjected to elaborate investigation and a sumptuous publication of results, the increase of knowledge and the precise measurement of effects, which had only been recognised in a qualitative and even uncertain way, was very largely instrumental in inspiring a change in our outlook on the fundamental principles of both the old and the new seismology.

Earthquakes have been a subject of study from early times, but the science of seismology, in its more modern sense, did not begin before the eighteenth century, and by the middle of the nineteenth the main principles had been established on which all further work has been based So far, however, the science had only dealt with the seismos which was known to and studied by the ancient Greeks-that is, the disturbance which can be felt, which may cause damage or destruction to the works of man, or may alter the features of a landscape, according to the degree of violence attained, but in the last decade of the century a new seismology was born. The incarnation of this new science may be dated from the discovery, by Rebeur-Paschwitz, that records could be obtained, with suitable instruments, of disturbances, evidently connected with destructive earthquakes, at places far beyond the region in which even the feeblest manifestation of the work could be detected by the unaided senses of man; and by the

beginning of the following century it had been well established, and generally accepted, that these distant records revealed the existence of three distinct forms of wave motion, travelling at different rates and along different paths, from the origin to the place of record. This is the foundation on which has been reared the whole superstructure of that newer seismology which has shown us that the earth is composed of a series of concentric shells of materials, differing in physical character and, presumably, in chemical composition; which has given rise to investigation of the character, and revealed the existence of previously unsuspected forms, of wave, and to other results which only a generation that has forgotten, or chosen to ignore, its Greek could describe as seismology, but are equally interesting and important by whatever name they may be called.

Nor has the older seismology stood still report on the Californian earthquake of 1906 still belongs to the period of foundation-laying. The work was dominated by the idea of a centre of origin, though this was no longer regarded as of such limited dimensions that it could be treated as a point; it had become a fissure extending for a length of nearly 300 miles, but was still regarded as the origin both of the destructive earthquake and of the distant records. The cause, too, was regarded as the shock resulting from fracture, due to a slowly growing strain, which had gone on accumulating, with occasional partial relief, for a period of at least a century. A re-examination of the record of older earthquakes, and the study of more recent ones, has altered this; it has been found that, in destructive earthquakes, the origin of the surface shock is not so simple as had formerly been supposed, that instead of being a single fracture, or limited to the central portion of the affected area, the origins are often very complicated and spread over a large proportion, even to almost the whole, of the tract over which the shocks can be felt; it has also been found that the origins of the surface shock and of the unfelt distant record are by no means the same. The destructive earthquake can be proved, by local observations, to be of very shallow origin, generally, if not always, of less than ten kilometres in depth, and the same is true of the great majority of shocks which can be felt but do not cause damage or give rise to distant records. The disturbance which is registered at long distances has been shown, by the great series of observations studied, especially by Prof. H. H. Turner, to originate at depths which must be

measured in hundreds of kilometres, and the examples are steadily increasing in number where the geographical position of the origin of the longdistance records does not agree with that of the greatest violence of surface shocks, but may be at a considerable distance, even to a hundred miles or more Yet the two are evidently in some way connected with each other, and if we liken the origin of one to the discharge of a great gun and of the other to the explosion of its shell, it is easy to see that the disturbance produced by its own charge of explosive would be very different from that which would result if it happened to strike an ammunition waggon or dump. In this way we may dimly realise the connexion between the long-distance record and the earthquake proper, and may find an explanation of the fact that there seems to be no quantitative relation between the two, a highly destructive earthquake may give a small record, while a much larger one may accompany a disturbance which is only felt as a moderate and harmless shock near the origin.

Such, in brief outline, is the scheme on which a useful and interesting book might be written. Dr. Davison, in dealing with the works only of those individuals who are no longer living, has adopted a safer and probably more permanently serviceable line This course is not devoid of inconvenience, for the end of some has been so recent, in two cases so late as 1923, that their work belongs as much to the building of the superstructure as to the laying of the foundations, and the absence of reference to the work of those still with us leads to a very partial and even misleading aspect of the present state of our knowledge. This, however, forms but a fraction of the work, the rest of it gives us something that was much wanted A general knowledge of the early history of the subject of his study is useful to every worker, but for each to go separately through the old literature would be an unjustifiable reduplication of toil, which Dr. Davison's work has rendered unnecessary. An extensive and, what is more important, an accurate reader, Dr. Davison has in pre-eminent degree the knack of extracting the nutricious kernel from the husk and shell in which it is clothed, and of expressing clearly those results which are of permanent interest or importance. He has produced an excellent account of the early history of the study of seismology, which contains what every serious worker at the subject ought, and all that, except for very special research, he needs, to know, of these older works and workers. R. D. O.

## Newton and Descartes.

- (1) Sir Isaac Newton a Brief Account of his Life and Work. By Prof S Brodetsky. Pp xii+161 (London Methuen and Co, Ltd, 1927) 5s net
- (2) La vie raisonnable de Descartes Par Louis Dimier (Le roman des grandes existences, Tome 5 ) Pp vi+281 (Paris Librairie Plon, 1926.) 15 francs
- (1) PROF BRODETSKY has followed up his great success in organising the Newton celebration at Grantham by publishing what is easily the best short book on Newton's life and work. It is really even more than this, for it would be difficult to find anywhere a clearer and more instructive account of the genesis and meaning of the differential and integral calculus, as well as the way in which the law of gravitation brings together and completes the work of Galileo and Kepler. All this is done by a first-rate mathematician with a turn, like his hero, for the practical and applied side of mathematics.

To have accomplished this, with a lively narrative of Newton's personal life and all the relevant public occurrences of the time, within a compass of 160 pages, is a remarkable feat, and it is to be hoped that Prof Brodetsky will go on to employ the talents which he has revealed in this volume by treating some other of the great figures in science in the same way Nothing could be more stimulating to a young student than to read and re-read this book, mastering the admirably simple diagrams and looking up the references to contemporary thinkers with whom Newton was in touch. It is, in fact, a model of how the history of science should be presented—short, interesting, personal, suggestive, and competent. It does not attempt to cover the ground of the sciences which Newton studied and advanced, but it illuminates the advance and creates at every point that most wholesome of all appetites—the desire to know more.

To the student of general history, the connexions with other contemporary events, with which Prof. Brodetsky rightly and richly sprinkles his pages, will be specially welcome, for they help to build up the growing idea of the unity of history, and they show also how easily and in what small space it may be done, if we set out to do it and have the requisite knowledge. Newton's general philosophy fits in with that of Milton, whose "Paradise Lost" was completed at the same moment as Newton's two capital discoveries, Newton practised jumping with and against the gale in the storm which accompanied Cromwell's

death; the first part of the "Principia" was published just as Charles II. was dying, and with the *imprimatur* of Samuel Pepys; and so on

Une œuvre de vulgarisation du premier ordre

(2) Close on Prof. Brodetsky's popular account of Newton comes a short French book on Descartes which offers other points of interest. M Dimier, as compared with Prof. Brodetsky, is literary, personal, and, above all, Catholic His book is beautifully written in a terse, pointed, and unadorned style, and Descartes is a still more unqualified hero to him than Newton is to the English writer.

Two capital and connected points are aimed at in the treatment. first, that Descartes' thinking was essentially synthetic and religious; second, that he was primarily inspired in his philosophic work by a desire to combat the popular scepticism of the day.

If one makes due allowance for the one-sidedness and exaggeration of this view, one may certainly gain a good deal of sidelight both on Descartes' work and on the life and thought of his time.

It is true—on the first point—that Descartes was primarily metaphysical and philosophic, whereas Newton was primarily mathematical and positive. Newton was above all concerned to make sure of his conclusions with regard to a particular law or set of observed facts. Descartes was from the first seeking to know, and to connect the whole of his knowledge in one coherent and unassailable This is in general the difference between the philosophic and the scientific approach, and it may be paralleled in the nineteenth century by the difference in the attitude and the influence of two leading men-again a great Frenchman and a great Englishman - Comte and Darwin. each case the influence of the philosophic type is more diffused and indirect, and of the scientific more direct and constructive of fresh scientific truth.

On the Catholic question which pervades the book before us, it is sufficient to say that while Descartes was never anti-Catholic or sceptical, and conceived his main work to be the establishment of a body of certainties on a deistic basis, yet he certainly did not start from theology but from mathematics. His philosophy was inspired by mathematics, and he feared assaults from Catholic critics as much as from the Calvinists who got up a great case against him in Holland. On the details of all this and of his correspondence on moral questions, M. Dimier is instructive and interesting, and well deserves to be read.

F. S. Maryun.

The Chemistry of Petroleum.

The Scientific Principles of Petroleum Technology
By Prof. Dr. Leo Gurwitsch Translated and
revised by Harold Moore Pp xvi+470+8
plates (London Chapman and Hall, Ltd,
1926.) 25s net

FURTHER addition to petroleum literature A is at the present time almost a challenge to criticism, in view of the voluminous writings extant on every possible branch of the subject, only flagrant heresy and iconoclasm, a brand-new theory of origin, for example, would seem to justify a new text Though this book claims neither excuse, it is acceptable for three good reasons. that it has been an authoritative German text since 1912, revised in 1924, and now admirably renovated for the benefit of English readers by its translator, Mr Harold Moore, that it presents the European and not the American viewpoint, and that it is less concerned with commercial oil-refining than with the scientific principles on which that industry The author holds high academic office at the University of Baku and, as might be anticipated, his writing is coloured with experiences of Russian petroleum and biassed to the work of European colleagues, truly a refreshing departure from recent tendencies.

We have here a real text-book of the chemistry and physics of petroleum, two remarkably complex subjects when considered for their own sakes and not for their economic applications; in fact, one of the features of this volume is its indication of the enormity of unfinished research, of work still to be done, of knowledge yet to be gained, before we can claim understanding As a text-book it leaves little to be desired Carefully arranged, lucid in style, concise in presentation, entirely technical but never fogged with petty detail, masses of formulæ or wild speculation, the work makes an immediate appeal and deserves, as it will undoubtedly achieve, a place in the front rank of English literature on the chemical technology of petroleum.

The discussion centres on three main factors: raw material, manufacture, and products, each treated from the scientific viewpoint, i.e the first principles involved. Petroleum, the raw material, is first reviewed and its chemistry and physics explained so far as this is at present possible. Manufacture concerns essentially distillation processes and sulphuric acid refining. The products benzine, illuminating and lubricating oils, paraffin wax, and vaseline are similarly described. While

P. Landing

theory and experiment remain uppermost throughout, the rationale of industrial operation is not neglected, but rather follows as an illustration of the doctrines expounded.

Deficiencies there are bound to be in a work of this character, but they are for the most part innocuous: the treatment of sulphur and nitrogen compounds is poor in its brevity (pp. 113-119), likewise mert gas components of natural gas (p. 124); the misuse of the geological term weathering as applied to evaporation of petroleum (p. 175); the data of crude oils of the world are antiquated and there are serious omissions of Mid-Continental and Colombian crudes (Ohio-Indiana is not the accepted Mid-Continent field); the use of the term 'resm' (p 200) for the asphalt-content of Balachany oil is misleading and should not be allowed to confuse an already clumsy and 'muddy' nomenclature, the section on products is far more sketchy than the rest of the text, especially in regard to the vital subject of lubrication. All this pales, however, by the excellence of the translation and the esteem which one instinctively feels for one who is a master of a particularly complex subject Prof. Gurwitsch is fully entitled to renewed congratulations.

# Our Bookshelf.

The Epic of Mount Everest. By Sir Francis Younghusband Pp 319 + 16 plates (London: Edward Arnold and Co., 1926.) 7s. 6d. net

SIR Francis Younghusband has written a concise and inspiring account of the three expeditions which were organised by the Royal Geographical Society and the Alpine Club. The first expedition reconnoitred the mountain in 1921, the following year the second expedition attempted to climb the mountain, but failed to reach the summit. At the climax of the third attempt, in 1924, Mallory and Irvine were seen for a moment climbing fast, and within reach of the goal. Did disaster overtake them before or after they accomplished their task? Unless those two gallant climbers did in fact reach the summit, and left a record there, the mystery may never be solved.

The author makes it clear that the ascent of Mount Everest is possible, and the mountain will eventually be climbed. He attributes the failure in 1924—if indeed it was a failure—to two causes. The first was the exhaustion of the best climbers in the gallant rescue of four porters, who had lost their nerve in coming down from Camp IV. The second was the attempt to use oxygen. Oxygen does not increase the strength of a climber sufficiently to make up for the weight of the apparatus.

Though the ascent of Everest is possible, it can never be easy or safe. Only the toughest and

most determined climbers have any chance of reaching the summit, and to do so they must first acclimatise themselves to altitudes of more than 20,000 feet. In order that the climbers may reach the last stage in good condition, at least six camps must be established between the base at 17,000 feet, and the jumping-off point at above 27,000 feet. This involves the use of a large number of porters; the 1924 expedition employed seventy, but had not enough. Finally, the weather must be propitious.

There can be no doubt that, if the Tibetan authorities once more open the road to the mountain, Everest will be attacked again and again, until it is vanquished. The victory will not add anything to human knowledge, or to the material wealth of the world. But the mountain offers a perpetual challenge to the boldest climbers. To use Sir Francis Younghusband's own words, "Everest stands for an adventure of the spirit." Yet amongst those who, from the scorching plains of India or the arid plateau of Tibet, lift up their eyes unto the hills, there may be some who mutely hope that the uttermost peak may never be desecrated by the foot of man; and that also is an affair of the spirit

Essentials of Volumetric Analysis. an Introduction to the Subject, adapted to the Needs of Students of Pharmaceutical Chemistry. By Prof. Henry W. Schimpf. Fourth edition, revised and enlarged by Dr Alfred I. Cone. Pp. xiv + 370 (New York: John Wiley and Sons, Inc., London: Chapman and Hall, Ltd, 1926.) 15s. net

As an introduction to the subject, this book doubtless covers the requirements of students of pharmaceutical chemistry. It does not, however, in matters of detail, arouse the reviewer's enthusiasm. The introduction of unusual abbreviations is confusing; the arithmetical examples are frequently expounded in an unnecessarily elementary manner; the use of exactly normal solutions, instead of the employment of a factor, is directed; the explanation of the use of excess of free acid in permanganate titrations is incomplete, so as to be quite mis-leading; the use of the symbol O<sub>3</sub>, except to in-dicate a molecule of ozone, is to be deprecated; the standardisation of N-sulphuric acid by titrating 10 c.c. with "recently prepared and standardised N-potassium or sodium hydroxide" is open to obvious criticism. In addition to the usual inorganic volumetric exercises, the analysis of sugars, oils, alkaloids, urea, formaldehyde, and organic nitrites is described, and a short section is devoted to the principles underlying the determination of hydrogen ion concentration.

A Treatise on Viticulture. By Prof. A. I. Perold Pp xi + 696. (London: Macmillan and Co., Ltd., 1927.) 25s. net.

ALTHOUGH written at Stellenbosch, South Africa, and dealing very largely with viticulture in South Africa, this work is also applicable to cultivators and students in other parts of the world, for the

author gives many particulars of outdoor vine culture in California, Australia, and Europe, and describes very fully the several species of Vitis from which the cultivated grapes have originated The book is not meant for the cultivator alone, but also for students, for it embraces all phases of the vine, passing from the historical, morphological, and biological, through the various processes of cultivation, to the preparation and marketing of the crop in the numerous forms in which it appears in commerce

Following a general introduction, the author discusses both the external and internal morphology of the vine, the descriptive matter being aided by good illustrations. More than forty pages are then devoted to biological questions, which include germination of seeds, the factors governing bleeding after pruning—a question that often gives considerable trouble in Great Britain if pruning be left rather late—development of shoots, fructification, the chemical composition of grapes, ripening of

wood, etc.

Chap. iv. deals with classification. Reference is made to the various genera composing the family Ampelidaceæ, then the numerous species of Vitis are reviewed, with special descriptions of those which produce grapes of commercial value, or are suitable for stocks on which to graft or bud cultivated forms or hybrids The numerous hybrids between American species are described and comparisons are made between them, and between them and the European and Asiatic forms of Vitis vinifera.

A special chapter then directs attention to details of propagation, and another to diseases and their treatment. Chap. x. deals with cultivation, giving special attention to manuring; whilst the following chapter describes methods of pruning and training. The remainder of the book is devoted to the products of Vitis and their prepara-

tion for the market.

The book is likely to prove of considerable value to students, cultivators, and others interested in the vines and their cultivation.

The Zeiss Works and the Carl Zeiss Foundation in Jena: their Scientific, Technical, and Sociological Development and Importance popularly Described. By Prof. Felix Auerbach. Translated from the fifth German edition by R. Kanthack. Pp. iv + 273. (London: W. and G. Foyle, Ltd., n.d.) 10s. 6d. net.

THE name of Abbe will probably remind most English readers of a certain theory of image formation in the microscope, perhaps also of some refractometers and other optical devices, but now that Prof. Auerbach has turned minstrel, and produced the saga of the Carl Zeiss Foundation with Abbe as the hero, protean, magnificent, we can scarcely escape the conviction that his hero's claim to greatness lies as much in sociology as in optics.

The fact that the first half of this well-illustrated book is a kind of conversational illustrated catalogue of the Carl Zeiss products and their history, an excellent advertisement through its atmosphere of

solid achievement and great potentiality, is not without significance in explaining the production of the English translation This part of the book calls for no particular comment, except that certain outside inventors whose instruments have been made by Zeiss might have been mentioned, to say The latter part of the book, however, the least will well repay any student of industrial organisation who finds time for its perusal As Prof Cheshire observes in his foreword, Abbe's scheme has now passed through the experimental stage It has survived the shocks of war and war's ending Its story is told with genuine feeling, not untouched by poetry, as befits a modern saga

The epilogue laments that "the German people are impoverished, their savings, large and small, are gone and their purchasing powers have dwindled to the lowest level "Several pages in the book are devoted to a description of the Zeiss planetarium, and we now hear that at least eleven German cities Those who know have ordered such instruments the cost of these will have much more respect for the purchasing power of the German people than

seems to be the lot of Prof. Auerbach.

An Asian Arcady: the Land and Peoples of Northern Siam By Reginald le May. Pp. xiv+274+64 plates. (Cambridge: W Heffer and Sons, Ltd.; London: Simpkin, Marshall and Co., Ltd , 1926.) 21s. net

Northern Stam—the Lao country—has received little attention from travellers, and although the teak trade has attracted not a few Europeans, information about it is scanty. This is the more to be regretted as it well deserves Mr. le May's designation of 'Arcady,' and its people ethnologically present many points of interest. This account of the country and its people is therefore welcome, especially as it is illustrated by a large number of excellent photographs. The author has dealt with his subject historically and analytically in an ethnographic account of Lao customs and beliefs, which, though not systematic, contains many interesting data; and descriptively, in an account of a journey through the country. He has also included extracts from the references of early travellers. The first of these is Marco Polo, who, however, did not visit the Lao himself Lao were originally an offshoot of the Tai from China, and ethnologically they stand midway between the Shan and the Siamese. Nominally Buddhist, their beliefs are largely animistic, with a firm belief in the power of witches. A characteristic practice is that of roasting the mother of a new-born child, a custom also followed in the Malay peninsula—in a recently reported case with fatal results.

Racial Origins of English Character: with an Appendix on Language. By R. N. Bradley. Pp. 192. (London: George Allen and Unwin, Ltd., 1926.) 6s. net.

WHETHER mental qualities can be associated with racial characters is a question to which both anthropologists and psychologists have recently devoted

considerable attention, but with no marked result Yet it is a matter of some moment, especially in the application of the results of science to the practical affairs of life. Mr. Bradley, boldly ignoring difficulties, has presented his readers with an analysis of the English character and achievement in the various departments of life-religion, politics, literature, science, and art—which is based upon the racial differentiation into Nordic, Aloine, and Mediterranean. He has an acute observation, a wide knowledge of his fellowcountryman, and a pretty sense of humour courage in essaying a difficult task will no doubt receive its due reward in a shower of hostile criticisms; but we hope that his critics will at least be grateful that he has given them something to criticise and that his mistakes may lead to the elaboration of a sounder method Mr. Bradley, in evaluating racial character, relies upon material which ultimately is based upon impression the psychologist can devise some objective method of determining and evaluating racial mental characters, study of the question is rendered nugatory by the personal equation.

Leitfaden der praktischen Experimentalphysik fur Vorlesung und Unterricht. Von Dr Reinhard Mecke. Unter Mitwirkung von Dr. Anton Lambertz Pp. vi + 195 (Berlin: Julius Springer, 1926.) 9.60 gold marks.

This useful work is a reprint of the technical advice concerning physical lecture experiments given in the introductory volume of Geiger and Scheel's handbook of physics, which has appeared in 24 volumes. It describes 533 lecture experiments covering the whole range of physics. Many of these are new, and in all of them due consideration is paid to the modern resources at the disposal of the experimenter. This applies particularly to the thermionic valve. We notice elegant methods of demonstrating stream lines by means of coloured liquids, the Johnsen-Rahbek effect of friction due to small currents, experiments with the speaking arc, and some very pretty and ultramodern spectroscopic demonstrations. A valuable feature of the book is the addition of the essential definitions and formulæ, together with the chief numerical data As the work is not a text-book of physics, nothing but what is essential to the success of the experiments is given, and given in the smallest compass. But wherever desirable, references to original papers or text-books are appended. Altogether an admirable book.

The Caves of Mendip. By H. E. Balch. (The Somerset Folk Series, No. 26.) Pp. 82+18 plates. (London. Folk Press, Ltd., 1926.) 2s. net.

In this little book, which forms one of a Somerset Folk Series, the author, whose work in cave exploration has long been so well known in the west of England, gives a fascinating account of what he terms elsewhere the 'Netherworld of Mendip.' Some of the adventures described, such as those in the Lamb Lair, Harptree, and in Eastwater Swallet,

show that cave exploration may afford all the risks of mountaineering with the additional possibilities of getting drowned or wedged in a narrow passage. An impressive point is the evidence given of the existence of vast caves which have never yet been reached The cave to which most space is allotted is naturally Wookey Hole, and a few illustrations of the remains left by its Palæolithic and later inhabitants are reproduced from the author's larger work on the subject Other illustrations are from photographs by Mr. J. H. Savory, to whose keenness and skill all Somerset spelæologists owe so much The author points out that much work is in progress or remains to be done on the caves of the Mendips, and in this connexion allusion may be made to the admirable work carried out since the War by the Spelæological Society of the University of Bristol

Elementary Algebra By F. Bowman. Part 2. Pp viii+431. (London Longmans, Green and Co, Ltd, 1927.) 6s.

The second part of Mr Bowman's "Elementary Algebra" contains much of the modern analysis which is generally known as 'higher algebra.' Beginning with convergency and the usual series, he passes on to the complex variable and eventually discusses the fundamental theorem of algebra that every equation has at least one root. The consequence of this arrangement is to bring determinants, permutations, and combinations at the end of the book.

The treatment throughout is admirable, especially in the chapters on convergency and complex numbers. Geometrical illustrations are used in an instructive manner and care taken to clear up small points which create difficulties to beginners, e.g. on pp. 19 and 28.

It seems unnecessary to assume that students who are reading the algebra covered by this book will not be familiar with some analytical geometry and calculus, and the space given to these subjects might well have been used to give a fuller treatment of convergency and thus make the book more useful for those preparing for mathematical scholarships at universities.

Animal Mind. By Frances Pitt Pp. 340+22 plates. (London: George Allen and Unwin, Ltd., 1927.) 15s. net.

MISS PITT'S work is the modern version of the old anecdotal natural history which Edward Jesse and others made familiar to early-Victorian naturalists. But the new version is much revised and improved, for Miss Pitt's knowledge of the ways of common birds and mammals is deep, and in endeavouring to interpret habits and incidents she is seldom betrayed into the facile explanations which often satisfied the earlier writers. The observations are acute and reveal many striking facts well worth testing in a wider field, such as the response of the eating instinct of a young fox to the presence of a trace of fur, while plain flesh was ignored. The book is well adapted for the general reader as well as for the trained naturalist.

# Weber's Theory of Molecular Magnetism, and the Internal Field.

THE name of W. Weber is one of those outstanding continental names which are associated with epochs in the development of science, and are regarded with honour in Britain Yet in Britain there has been evident a considerable amount of misunderstanding regarding Weber's initiation of the essential features of the modern theory of molecular magnetism. That misunderstanding seems to have originated in an unfortunate wording of a remark made by Maxwell in his exposition and development of Weber's work "Electricity and Magnetism," vol 2, 2nd ed., p. 76).

The two essential features of the modern theory are clearly stated by Maxwell. First he says (p. 74): "Weber's theory differs from this in assuming that the molecules of the iron are always magnets, even before the application of the magnetising force." Secondly, he says (p. 76): "The molecules do not turn with their axes parallel to x (the direction of the magnetising force), and this is because each molecule is acted on by a force tending to preserve it in its original direction, or because an equivalent effect is produced by the mutual action of the entire system of molecules." It is the statement in the last clause which contains the second essential feature.

In addition, Weber adopted Ampère's view that the molecular magnetism results from molecular currents; and, to this view, modern physics has merely added the restriction that these currents

are convective.

In the first sentence quoted above from Maxwell, the first feature of the modern theory is explicitly ascribed to Weber: in the second sentence, the second feature is not directly ascribed to him. If that feature were not due to Weber, that sentence would, in accordance with the rules regulating scientific priority, fix it as the property of Maxwell and constitute him as the originator of one-half of the essential fundamental postulates of the modern theory. But Maxwell is making no claim for himself. In his next sentence he adds that "Weber adopts the former of these suppositions as the simplest.

This last remark clearly points out that Weber discussed the second feature. Therefore, unless he explicitly abandoned it, he was the originator of both of the basic postulates of the modern theory. Maxwell's words do not necessarily mean that Weber abandoned the second supposition. They only assert that he did not follow it out; and, further, that he did not do so because that supposition was not so simple as an alternative which was chosen by him.

Now the most minute search of Weber's paper (Pogg. Ann., 1852), word by word, reveals two facts-(1) Weber not merely, as Maxwell implies, asserts the second feature of the modern theory, he reiterates it again and again; (2) Weber not merely avoids any choice between that feature and another one, for reasons of simplicity or otherwise: he persistently avoids the consideration of any alternative.

Therefore he, and he alone, is the author of the

modern theory of molecular magnetism.

Moreover, Weber was not merely the originator of

the fundamental ideas. He was their first developer. No later worker can do more than apply his views Weber himself illustrated the applicamore widely tion of these views, in two cases, by a formal development of the action due to a neighbouring molecule; and that application constitutes one of those gems of intuitive insight which characterise the work of the masters.

Therefore Maxwell cannot, in the sentences quoted above, apart from a serious misunderstanding, be ascribing to Weber a choice between a non-magnetic force and one of magnetic origin. That is perhaps the most natural interpretation of his words, yet he does not explicitly mention a non-magnetic force any more than does Weber. That idea was introduced

by other workers.

Weber did make one choice, and that evidently for reasons of simplicity as Maxwell said, though he did not state them as such In speaking of the force which must be acting so as to drive back a magnet to its position of equilibrium when it has been deflected from it through an angle  $\phi$ , far from saying a non-magnetic force, he says, "But this back-acting force, arising from the inutual actions of the molecules, must increase with the deflection, and can be represented by  $D \sin \phi$ , where D denotes a constant magnitude which one can call the molecular directive

force" (p 166).

That is Weber's direct assertion in introducing the very expression for the resultant force with which Maxwell deals. Therefore, as above stated, Maxwell could not possibly assert or mean that Weber abandoned the view that the force had a source apart from the mutual molecular magnetic On the other hand, it is to be noted interactions that Weber's theory fixes the expression for the force whenever the distribution of the surrounding molecules is given. The thing that Weber definitely avoided, and that for the sake of simplicity alone, was the necessarily laborious evaluation of the true expression for the internal field. He took the only other possible method of approved scientific exploration, the method of postulation of a simple and sufficiently approximate expression for it. Maxwell, apart at least from an accidental failure to notice Weber's own statement regarding the nature of D, could mean nothing olse than that; but the wording of his statement can unfortunately lend itself to the other interpretation.

The incorrect supposition that Weber abandoned the idea of mutual interaction of the molecules by means of their magnetic fields alone has not been quite universal in Britain. Jeans, for example ("Electricity and Magnetism"), describes the correct

position with great clearness.

The later development of the subject by Ewing was largely directed towards the illustration, by means of models, of that mutual interaction of molecules which Weber first put forward, and against all postulates of the existence of quasi-clastic forces which had been made by certain other writers, amongst whom, however, Weber is not to be found.

The task of subsequent work is the evaluation of the force symbolised by D. Weber made the most drastically simplifying postulate regarding it. He assumed it to be constant, and found the result to be in agreement with observation in the case of soft iron: and he insistently reiterated the statement that he was dealing only with non-retentive iron. It was Maxwell who pointed out the over-stringent nature of Weber's postulate if retentiveness is to be taken into account, and he widened it accordingly. That was Maxwell's work, not Weber's, and in it he followed Weber in tentatively assuming a simple

form for the law rather than determining it by mathematical development, which the state of experimental knowledge at the time could scarcely

justify.

In the more recent development of Weber's ideas the question has been again raised whether the internal molecular magnetic field is sufficient to account for observed phenomena. Thus Weiss, who adopted Weber's assumption regarding the internal field to fit it for application to crystalline media, was led by thermomagnetic phenomena to ascribe very high values to the internal field relatively to even strong external fields. He afterwards pointed out that the high values may include equivalent values of fields which are actually non-magnetic, but may, for example, be electrostatic if the molecular magnet is also an electric dipole, and this view leads to values of the molecular electric susceptibility which are consistent with results of observation.

Now an application of Weber's theory to a determination of the actual law of force, due to the mutual actions of the molecular magnets in a homogeneous crystal, readily indicates that the magnitude of the internal field is of the same order as that of fields which are normally used in the investigation of the magnetic properties of substances. It shows, even without numerical evaluation, that the least possible value of an external field which is able to magnetise a cubic crystal in any direction relative to its crystalline structure is equal to five-eighths of the maximum That is to say, the maximum internal internal field field acting upon a molecular magnet is not twice as strong as the external field which is just able to turn the molecular magnets out of their stable directions, and so to magnetise the crystal in any direction. This is true whatever be the nature of the internal directive field which tends to maintain the magnets in their stable positions. If that internal field has in part an electrostatic origin, the remaining magnetic part is proportionately smaller

This is in accordance with the observations, described in a recent issue of NATURE (Mar. 5, p. 353), on the deflexion of  $\beta$ -particles in their passage through

thin magnetised nickel foil.

If we postulate that there is equipartition between the average translational energy per degree of freedom of the molecules and the average rotational energy of a molecular magnet, the axis of which is maintained, in consequence of the heat motions, on the average at an angle  $\phi$  with the direction of the resultant field, we find, on evaluation of the internal field, that, at ordinary temperatures, this postulate is not satisfied. The change of potential energy of a molecular magnet, due to the rotational effect of heat motions, amounts only to about 1 per cent. of the energy per degree of freedom. This seems to indicate that the internal structure of the molecule is such that, in the collisional interchange of energy amongst molecules, only about 1 per cent. of the whole is communicated to the subatomic portion of the structure which is concerned with the manifestation of magnetic quality. W. PEDDIE.

Univ. Coll., Dundee.

#### Evolution: Emergent and Resultant.

The recent articles by Dr. P. Chalmers Mitchell and Prof. C. Lloyd Morgan (NATURE, May 21, p. 748, and May 28, p. 786) clearly show the increasing importance of the problem of emergence. But it seems to me that Prof. Morgan advances a criterion of emergents which is seriously defective, and so

prevents any reconciliation of the opposed viewpoints. In the first place, he appeals to "matters as they now are," and quite apart from what future discovery may reveal. It follows, therefore, that as knowledge expands, much that is now regarded as emergent may prove to be resultant, since it will become deducible from the phenomena of some "earlier phase"; and to this progress no limits can be assigned in advance.

This attitude is plainly an appeal to the ignorance which prevails at any given moment, and it at once destroys any absolute distinction between the emergent and the resultant. Now the trend of research, in my opinion, undeniably involves this loss of absoluteness, as Dr. Chalmers Mitchell maintains For while it will always be impossible to deduce the macroscopic qualities of combinations from the macroscopic qualities of their elements, the more complete knowledge of microscopic and ultra-microscopic qualities does enable the qualities of combinations to be both explained and predicted. In this respect success depends on the capacity of the inquiring mind; so that as mind evolves, emergents must give way to resultants. If, for example, we accept Prof. Morgan's criterion, then to Galileo electromagnetic storms, due to solar radiation, would be emergent, while to us they are resultant. Similarly, many of the phenomena presented by vitamins, not being as yet deducible, are still emergent, but will probably be resultant for future bio-chemistry.

The criterion of being, or not being, deducible is thus wholly relative and transient; and it obscures what I take to be the sole genuine attribute of all emergents, whether deducible or not; that is, uniqueness, or the possession of characters previously unprecedented. From this more inclusive and unprecedented. permanent viewpoint, atoms and crystals emerged, exactly as did life and sentience at still later stages; and this quite apart from the partial, or complete, explanation of their origin. For each of these was, when it first appeared, in its own specific way unique, exactly as "Hamlet" would remain unique even though it could be fully accounted for in terms of Shakespeare's life and character. Such absolutely unique combinations occur, of course, throughout the entire universe, and present one of its most marvellous and significant features. So that although "out of three sounds he frame, not a fourth sound, but a star," still

A star's a star for a' that.

J. E. TURNER.

University of Liverpool, June 16.

IF there be a valid distinction between resultant and emergent advance the question arises: How may this distinction be expressed with precision and clearness? One way of expressing it is that developed by Dr. Broad. It comes to this. There are certain integral wholes, composed of constituents in specific relations, of which it may be said that their characterising properties are not deducible from the most complete knowledge of the properties of the constituents taken severally in isolation, or taken collectively in some other set of specific relations. Such a whole is said to be emergent The theory of emergence is on trial. Of it Dr. Broad says that "it is a matter of controversy whether it actually applies to anything"; but he adds that it embodies "a logically possible view with a good deal in its favour." If, then, the theory be on trial as a scientific proposition and such it purports to be-it must, I submit, be tried out on the basis of existing scientific knowledge. I should not designate this as an appeal to ignorance.

Dr. Turner suggests that, instead of saying that the emergent, as something distinctively new, is not deducible from the data afforded by our present knowledge of the old—the characterising properties of the living organism, for example, not deducible from our existing knowledge of not-living entitiesit would be better to say that the character of the emergently new is unprecedented. One should welcome any suggestion that may conduce to clearness and precision But some may ask in what respect the unprecedented differs from the not-deducible Has it a wider or a narrower reach? Were I to use the word 'unprecedented' it would have for me a wider reach, since there are quite possibly, and I think very probably, thousands of instances in which some given mode of the algebraical summation of resultant features has never occurred before, and is, in that sense, unprecedented. But if this be so, we have here no criterion of that which is emergent as distinguished from resultant.

It seems, however, to be Dr. Turner's opinion that whereas the notion expressed by 'not deducible' prevents any reconciliation of opposed viewpoints, the implication of 'unprecedented' may tend to further such reconciliation. What, then, is this implication? It may be such as Prof Alexander, Dr. Broad, and Prof Whitehead would gladly accept But we need a clearer statement of what unprecedented means and all that it means. In view of reconciliation, is there some implication, which Dr. Turner surmises may be taken for granted?

C. LLOYD MORGAN.

#### Adsorption Isothermals.

In his book "Colloid and Capillary Chemistry" (page 111 of translation by H. Stafford Hatfield, London, 1926) Freundlich remarks in reference to the adsorption of gases: "a theoretically well-founded equation, giving the a, p curves over a considerable range, is not known. The empirical general parabolic equation  $a = ap^{1/n}$  in which a and 1/n are constants, is still nearly always used." The quantities a and 1/n are functions of the temperature and are constant when this is constant.

Freundlich refers to the theoretical studies of Polanyi, Langmuir, A. M. Williams, and others, and quotes the equations for the adsorption isothermal which some of these workers have proposed.

One naturally hesitates to introduce another equation into the field, but feels encouraged to do so if the new formula appears more suggestive than the older ones. I have recently been much impressed by the manner in which

$$a = \frac{f(T)p^{T/273x}}{1 + \phi(T)p^{T/273x}}$$

agrees well with experimental observations in a variety of published cases. In this equation a has its usual significance, the amount adsorbed; T is the absolute temperature of the experiment; f(T) and  $\phi(T)$  are functions of T, being constant when the temperature is constant; p is the equilibrium pressure of the gas, or may be replaced by c, the equilibrium concentration, for cases of adsorption of solute from dilute solution. Clearly if  $\phi(T)$  is positive the amount adsorbed attains a saturation value, but if  $\phi(T)$  is negative it becomes infinite at a certain pressure.

The symbol x is of interest. It is often actually unity, and in all cases that I have so far examined, exceedingly good agreement with experiment has resulted when x has been given a low integral value, as shown by the following:

No. 3011, Vol. 1201

Adsorption of carbon monoxide, argon, nitrogen on charcoal	x = 1
Adsorption of water vapour on)	x = 2 or multiple of 2
cotton, wood, leather	mumple of 2
Adsorption of acetone in water on blood charcoal	x = 2
Adsorption of bromine in water on blood charcoal	x = 2
Adsorption of isoamyl alcohol in water on blood charcoal	x = 4
Adsorption of benzoic acid in benzene on blood charcoal	x = 3

It should be noted that when the formula now proposed is substituted in Gibbs's adsorption formula.

$$a = -\frac{c}{RT}\frac{d\sigma}{dc},$$

we arrive at the following equation showing the effect of concentration on the surface tension of a solution:

$$\frac{\sigma_M - \sigma_L}{\sigma_M} = \frac{f(T)}{\phi(T)\sigma_M} R \cdot 273x \log \left(1 + \phi(T)c^{T \cdot 273x}\right),$$

which reduces to the empirical formula put forward by V. Szyszkowski (Zeits f. physik Chem., 64, 285; 1908) when T=273 and x=1.

Some years ago I had occasion to make measurements of the absorption of radiant energy from a stream of full radiation, temperature  $373^{\circ}$  absolute, by gases and vapours, and obtained data, more complete than any found published at the time, showing the variation of the proportion of the energy absorbed with the pressure of the absorbing gas in a column of constant dimensions. The equation suggested in the preceding for the adsorption isothermal can be applied with success in this case; T is the temperature of the radiation, p is the pressure of the absorbing gas, a is the energy absorbed, x=1 for carbon dioxide, benzene vapour, x=2 for water vapour. It is not difficult to conceive a relationship between the phenomena of adsorption and of radiation absorption.

The nature of my employment does not permit me to devote much more than my lesure hours to a study of this kind, and I shall be glad to communicate to any interested worker who may have facilities to pursue the matter both experimentally and theoretically, such results as I have, so far, been able to accumulate.

H. Bradley.

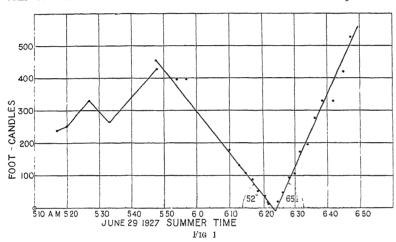

The British Boot, Shoe and Allied Trades Research Association, 19 Bedford Square, W C.1.

#### The Mechanism of Enzyme Action.

For a long time two viewpoints regarding the mechanism of enzymatic activity have profoundly influenced our conceptions in this field. To Oscar Loew is due the credit for the original suggestion that the enzymes possessing atomic groups with kinetic lability are able, even at a comparatively low temperature, to perform chemical action. This suggestion was later abandoned more and more, and we now generally assume that, as in the case of heterogeneous reactions, the reactants are adsorbed by the enzyme in order that reaction may ensue. In accordance with this we believe with Bayliss that the reaction velocity is determined by the concentration of adsorption complex, that is, reactant—enzyme, present in the system. The possibility of carrying out such reactions depends doubtlessly on certain conditions of the surface, which are also profoundly influenced by the hydrogen ion concentration.

Preliminary experiments carried out with certain zymase solutions which behave as lyophile colloids confirm this assumption. The reactivity of these solutions could be increased in such a manner that in laboratory tests the first stage of the reaction of zymase, for example, on glucose, produces 4, 5, and more c.c. of carbon dioxide per minute, so that a cell-free zymase solution can easily be prepared which will produce (using 20 c.c of the zymase preparation containing 5 per cent. of the substrat) 100 c.c or more of carbon dioxide in less than one hour. Similar effect of increased production of oxygen was obtained by the decomposition of hydrogen peroxide by means of catalase from fresh tobacco leaves.

The reactivity of the surface of the enzymes concerned in this reaction may be tremendously increased by appropriate peptisation, and the velocity of the reaction later undergoes a decrease which cannot be due yet to the decreasing concentration of the reactant Further experiments have shown that this capacity to react in an intensive manner can be maintained, within certain ranges, in both cases by working with living cells or with the colloidal cell-free solutions. The

experiments carried out indicate that certain chemical compounds are capable of forming an adsorption film on the surface of the enzymes which has the rôle of a protector (F. F. Nord, Protoplasma, 2, No 2; 1927). It might thus be assumed further that certain compounds which are supposed to have the effect of an 'activator' of an enzymatic reaction are in reality not activating the reaction, but only insufficiently protecting the enzyme from the damaging effect of intermediate or final metabolic products of the reactions concerned. It might be regarded, therefore, as correct to assume that regardless of the absence or the presence of a protector, which might even be a specific protector, there is always a certain concentration of enzymes present which is potentially capable of acting However, since the reactivity of the enzyme is dependent on its surface activity, it undergoes immediately with the initial reaction alterations which decrease relatively the velocity of the reaction independently of the concentration of the reactant In the course of the reaction the ratio between active and 'damaged' enzyme may decrease more and more below 1. Our present experiments have shown that it is possible to delay the speed of the reaction reflected in the change of the quotient noted above.

Since the most favourable conditions for the performance of an enzymatic reaction are in most cases not known, the statements above suggest the conclusion that in a great number of so-called 'activations' of enzymatic reactions by means of chemical compounds, in fact no 'activation' takes place by influencing enzymatic reaction through these com-

pounds, but the so-called 'activators,' which appear to be really protectors, enable the enzymes to act under conditions which are more nearly those which might be expected to be prevalent in ideal cases

The experimental work has been carried out in collaboration with Kurt W Franke. The details will be prepared for publication in the near future.

# Photometric Measurements during the Total Solar Eclipse.

It occurred to me that it would be interesting to measure the illumination received by a horizontal surface exposed to the hemisphere of sky during the whole period of the eclipse

I had the good fortune to see the eclipse from a large flat field to the south-east of Bankfield There were Southport. Lane, some distant low houses to the north-west, and some distant trees to the west-south-west, but for the purpose in question it may be assumed that the white test surface, placed six inches above the ground, was exposed to the hemisphere of sky, except for the obstruction of light caused by my crouched body This was allowed for before the results were plotted (Fig. 1). The readings were taken by means of a daylight photometer (a lumeter).

Practically the whole of the sun's disc was visible for the whole of the time, but there was a haze all the time. Sometimes this haze was noticeably thicker, but for-

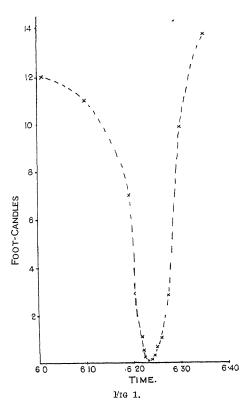

tunately this variation occurred towards the beginning and end of the readings. The regularity of the readings from 5.48 A.M. (with the exception of 5.57 A.M. when the haze was noted) to 6.47.5 A.M. seems to show that the haze must have remained constant during that period. My position when reading was north-east of the test surface, so that the direct sunlight was screened from the surface

It will be seen that the two inclined lines intersect at 6.24 A.M. (mid-totality), and that the line of decreasing illumination makes an angle of 52° with the horizontal, while in the case of the line of increasing illumination the angle is 65.5° This is due to the greater elevation of the sun during the latter period.

Several accounts of the eclipse refer to the "sudden switching off of the light at totality." This does not seem to be borne out by the curve. It was also thought by many that the light after totality was much greater than before. The curve does support this impression to some extent, but probably most of it was due to the physiological effect of the eye (pupil and retina) adjusting itself gradually to the decreasing light and then suddenly receiving the bright light after totality.

For the convenience of readers when studying the curve, it may be mentioned that at Southport on June 29, the sun rose at 4.47 A.M. Summer Time, first contact occurred at 5.30 A.M. Summer Time, and last contact at 7.21 A.M. Summer Time.

A S. E. ACKERMANN. 17 Victoria Street, S.W.1. The appended graph (Fig. 1) records the intensity of daylight during the recent total eclipse at Criccieth. The measurements were made by a Trotter photometer set up to face that part of the clouds which hid

the sun from Mr. A. Taylor and his colleagues at the observing station there.

The sudden onset and retreat of the darkness is well shown. The minimum recorded intensity (at  $6^{\rm h}$   $23^{\rm m}$ ) was 0.05 foot-candle, so that in 7 minutes after totality the intensity of daylight increased more than 270-fold.

Physiology Institute, University College, Cardiff.

#### The Hythe Skulls.

I am gratified by the letter of the editor of Biometrika in Nature of July 2, which suggests, though it does not say, that Miss Hooke did not mean to hint that I had wilfully selected certain skulls from the Hythe collection and discarded others which did not suit my purpose. This disclaimer was urgently needed. The suggestion of the editor that only the largest and thickest skulls had been picked out of the stack in 1851 is rather irrelevant, since the question of size is not the point.

What anthropologists who have quoted my paper are interested in is whether these skulls are broader and shorter than any other series of medieval or modern English people shows, and I submit that an average based upon 590 skulls, so long as the imputation of purposive selection is withdrawn, is not likely to differ appreciably from that of a like number recovered since. The question of whether it is advisable to deduce results from skulls which have been reconstructed from fragments, possibly crushed

and warped with damp, is quite an open one. In my experience the results are often grotesque caricatures of the original skull, and measurements taken from them are more likely to vitiate than to improve a fair average. In any case, the estimate of five years in which to piece together the fragments in the great stack at Hythe shows an optimism which, though I may admire, I cannot share. It might be done in fifty years, but the results would be quite untrust-worthy. Any one interested in these skulls will find a later paper of mine upon them in Archwologia Cantiana, vol 30, p. 203, in which I give my reasons for believing them to be largely of foreign origin, though I freely admit that in my first paper I assumed them to be those of Kentish people

F G. Parsons.

St. Thomas's Hospital, London.

#### "Index Kewensis."

I UNDERSTAND that it is not generally known that the Sixth Supplement of the "Index Kewensis" was published last year by the Clarendon Press. This includes references to the names of genera and species of flowering plants which were published during the five years 1916–1920, and also includes many which had appeared in previous years in publications which, owing to the War, were not available at Kew

As I have been informed that many sets of the "Index Kewensis" in botanical and horticultural libraries appear to be incomplete, and that in some cases supplements have been purchased for libraries which do not possess the original volumes, I have been asked to direct attention to the importance of the work. I would also point out that it is necessary, in order to keep abreast of botanical nomenclature, to possess all the supplements which have been published as well as the original "Index." Copies of the original "Index" or of any of the six

Copies of the original "Index" or of any of the six quinquennial supplements may be obtained from the Secretary, The Clarendon Press, Oxford.

#### An Early Reference to Continental Separation.

Those geologists who are interested in the Wegener hypothesis of the shifting of continents and the liters are of the subject may like to know that while reading an old book entitled "Eclipses, Past and Present," by the Rev. S. J. Johnson (James Parker and Co., 1874), I was rather surprised to find the following remarks: "If we study our earth carefully, we shall see that everywhere it bears marks of having undergone a fearful catastrophe. Fossil substances, which originally belonged to the sea, have been found on the heights of mountains; the bones of animals have been discovered in countries the most remote from those they inhabit. Again, if we look at our maps, we shall see the parts of one continent that jut out, agree with the indented portions of another. The prominent coast of Africa would fit in the opposite opening between North and South America, and so in numerous other instances. A general rending asunder of the world would seem to have taken place..."

I have italicised the important words.

W. WRIGHT.

24 Balham Park Road, S.W.12

# Stone Age Man in Kenya Colony.

By L. S. B. LEAKY.

In September 1926 I sailed from England accompanied by Mr. B. H. Newsam to investigate certam prehistoric sites which I had known of for some years in Kenya Colony. My expedition received financial aid from the Percy Sladen Memorial Fund and the Government Grant Committee of the Royal Society, the assistance of which is gratefully acknowledged. Stone tools of many types had been collected by myself and many others from the surface in Kenya Colony and the other East African territories for a good many years, and it was hoped that the work of the expedition this year would bring to light sites contaming stone tools associated with human remains

This expectation has been more than justified, as the following details will show, and it is hoped that the finds which have been made will prove suffi-

ciently important to call forth more extensive financial assistance, so that work may be continued in 1928 on a more comprehensive scale. A large number of further sites of great promise have been located. Until the specimens obtained have been brought to England and submitted to experts and carefully examined and compared with other prehistoric remains, it is naturally undesirable that I should make any definite statement as to the racial or cultural affinities of my finds, so the following general statement and outline must for the present suffice.

#### THE NAKURU SITE.

The first site excavated which yielded important results was situated on Major Macdonald's farm, Nakuru. Traces of ten burials were found in the lower levels of the deposit at depths ranging from 8 ft. to 12 ft. The majority of these human remains were veryfragmentary with the exception of Skull No. 3 and Skeleton No. 9, which was in an almost perfect state of preservation. This find was reported in the *Times* of Dec. 28 last. All the human remains found were definitely associated with a microlithic industry which I consider Mesolithic, and which bears striking resemblances to that industry in Uganda which Mr. Wayland has named Magosian. No attempt has been made to classify the tools out here, but this will be done immediately on arrival in England.

The skulls from the Nakuru site (see Fig. 1) do not resemble the skulls of the modern negro races inhabiting this country; nor, apart from extreme dolichocephaly, do they show any of the more marked characters usually considered typical of existing negro or negroid races. The face, instead of being short, is very long, but is not disharmonic

as it is proportionately broad, giving an upper facial index of 571. The nasal opening is only of medium width, the nasal index being 509. The nasal bones are long and are not flattened as in typical negroes, and there is a medium bridge. The lower margin of the nasal aperture has a well-defined sill and not the groove so common in negroid skulls

The mandible is remarkable in several respects. The horizontal ramus is very deep, especially in the region of the chin, which is very pronounced. The ascending ramus is also very high. This is largely due to, and necessitated by, the great height of the vault of the palate, which—measured from the chewing surface of the second molars—is 29 mm. This is remarkable, being as great a height as that recorded for Rhodesian man by Sir Arthur Keith ("The Antiquity of Man," vol. 2, p. 400). This

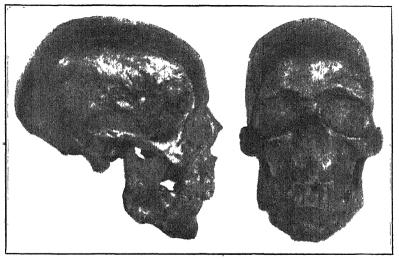

Fig 1.—Side and front views of Skull No. 9 from the Nakuru site.

measurement is given as being 7 mm. more than in the average English palate, while the average palate depth of six negro skulls measured locally is only 16.08 mm.

# THE ELMENTEITA SITE

The other site from which important results have been obtained is on Mr. Monroe's farm, Elmenteita. From this site the remains of at least twenty-six stone-age individuals have been recovered. The site is situated at the base of a small cliff below which there now runs a small stream. The bones were found in an alluvial sand, and were in a very disturbed state, being all mixed up and not lying in skeletal form. Five or six long bones, all femurs, for example, would be found lying in the same sand-filled crevice. Skull fragments and mandibles turned up in all sorts of odd corners with, here and there, pottery fragments and tools. It is at present difficult to account for this state of affairs, and the pros and cons of the various possible theories must be held over until a future date.

In the deposit with the human remains were found a number of obsidian tools mainly of a more primitive type than those from Nakuru, but including a few lunates and other Nakuru types. There was also a certain amount of pottery, some of it with the same decoration as found on the Nakuru examples, numerous animal bones, including skulls, mandibles, and teeth; disc shell beads, and one stone bowl similar to one of the Nakuru types.

At first it was thought that the skulls from the two sites were of the same type, but this is not substantiated by a close comparison made recently, although there are certain similarities. It is even doubtful if all the skulls from the Elmenteita site will prove to belong to the same race. Nevertheless, all the mandibles from this site show common characters, while they differ markedly from the Nakuru mandible

Skull A from Elmenteita is certainly different from Skull No. 9 from Nakuru. The photographs

graph. The similarities lie in the length of the skull as compared to the breadth, the cranial indices being 68·2 (Elmt) and 69 8 (Nak), the upper facial length, which is 80 mm. in both specimens, and the bi-zygomatic breadth, which in each case is greater than the maximum skull breadth, being 136 mm. (Elmt.) and 140 mm (Nak.)

Another skull type found at Elmenteita has a much broader skull, giving a cranial index of 76 It has a good forehead, and is orthognathous. This type, however, also differs from the Nakuru type.

Perhaps the most surprising feature of the Elmenteita crania is the narrowness of the nose as compared with the length. The four specimens upon which it is possible to take measurements yield the following results.

	Lengan	Bieautn	Tude z
Skull 'A'	$59~\mathrm{nun}$	$28~\mathrm{min}$	47 4
Skull 'B'	$60 \mathrm{mm}$ .	$24 \mathrm{\ mm}.$	40
Skull 'C'	$50 \mathrm{mm}$ .	$22~\mathrm{mm}$	11
Skull 'D'	$50 \mathrm{\ mm}$ .	$22~\mathrm{mm}$	44

These figures are certainly not those suggestive of negro affinities It seems doubtful even if those Negroid races which to-day have narrow noses can approximate to these figures

Full details of the work done and objects found will be published as soon as possible after our return to England in September with this season's specimens.

In Nature for Jan. 8, p. 61, there is a short note on my work based on a report in the *Times* of Dec. 28, 1926. This note contained some maccuracies and I would be grateful if I may be permitted to correct two of them. I am referred to as " of the Cutler Dinosaur Expedition" I am not a member of this expedition, nor, so far as I know, has

an expedition under such name existed out here. In 1924 I had the honour of being, for one year, a member of the British Museum East Africa Expedition which was excavating for Dinosaur remains in Tanganyika Territory under the leadership of the late Mr Cutler. Further on, reference is made to my "work in investigating stone-age remains in Uganda." Nairobi and Nakuru are towns in Kenya Colony, and it is regrettable that the archæological work in the two countries should be confused.

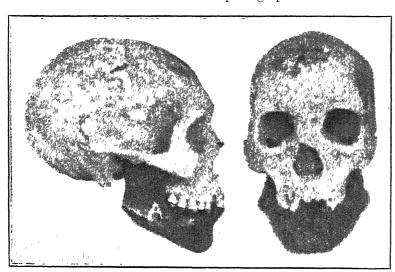

Fig. 2 —Side and front views of Skull A from the Elmenteita site

(reproduced as Figs 1 and 2) show both the similarities and the differences. In the Elmenteita skull the forehead is low and receding; the nose is much longer than in the Nakuru skull, while the width is much the same, this resulting in a lower index, which is actually 47.4. Moreover, instead of a sill at the base of the nose there is a groove; there is a trace of sub-nasal prognathism, the alveolar index being 103, the height of the vault is nothing like so great, while the mandible is of a quite different type. This is amply brought out in the photo-

# Some Difficulties in Relativity.

By Prof. S BRODETSKY, University of Leeds.

THE special theory of relativity was formulated by Albert Einstein twenty-two years ago. The general theory with its application to universal gravitation was published eleven years ago. The relativistic viewpoint has become an accepted principle and instrument in physical science. Yet

a complete understanding of the ideas underlying it is comparatively rare among laymen, and far from being universal even among men of science. This is natural, since the theory of relativity presupposes a break with preconceived notions, hallowed by unquestioning acceptance at the hands

No. 3011, Vol. 1201

of untold generations of experience and thought. We shall in this article consider a few of the difficulties that have come to the notice of the writer.

At bottom, the cause of all the difficulties assocrated with the special theory is the fact that the signals, which we have used from time immemorial for the purpose of correlating events at different places, travel so fast that it only became possible quite recently to measure their speeds. sound travels much faster than anything experienced in actual life until a few generations ago Light travels so fast, indeed, that to many people it is still a matter of surprise to hear that it is not instantaneous in its effects. Our primitive conceptions of time and space are therefore such as correspond to an infinitely fast signal, and a readjustment of ideas is required in order to reach conceptions of time and space that correspond to a signal that travels with finite and measurable speed.

Thus it appears to some people somewhat arbitrary to lay down the postulate that in empty space (infinitely far removed from the influence of matter) the speed of light must be the same to all observers, no matter what velocities they may have relatively to one another. Not everybody can visualise readily two frames of reference and argue from one to the other. Perhaps the argument will appear simpler if put as follows.

It is as much a fundamental of classical mechanics as it is of relativity mechanics that we cannot discover the absolute motion of a material body. Modern astronomy has long since discarded such views as the fixity of the centre of the earth, or of the centre of the sun, or of the centre of mass of the solar system, or of the centre of mass of the stellar system in which we live. We cannot say, therefore, what is the absolute motion of any material body, such as a long bench. Take two points, AB, fixed on this bench: Can we correlate the times at these two points? This is only possible by sending a signal from A to B. If Asends out this signal at, say, ten o'clock on his watch, B receives the signal and knows that it is then ten o'clock to A

The signal, however, takes some time to go from A to B, and naturally B will make a correction for this by saying that he receives the signal later than it leaves A, the delay being the distance AB divided by the speed of the signal. Now the bench AB is itself in motion in a manner which is quite unknown. Suppose that it moves with velocity u from A to B: then the speed of the signal relative to AB will be diminished by this amount, so that if its absolute speed is c the delay between A and B is AB/(c-u). But u is unknown. Hence the delay is unknown, and we reach the conclusion that it is quite impossible to correlate the times at A and at B!

We refuse to accept such a conclusion, because it destroys the basis of all natural knowledge. There are only two ways of escaping this conclusion. One is to suppose that c is infinite; the other is to assume that the speed of the signal relative to the bench is quite independent of the motion of the

bench, so that if this speed is called c, the delay is always  $AB \cdot c$ 

Now even if we could imagine or postulate a mystical signalling agency which travels with infinite speed, we must remember that scientific observations are made with the aid of instruments like telescopes and microscopes, which presumably cannot philosophise, and can only register events as impressed on them by natural agencies. All our observations, whether directly or with instruments, depend upon visual or optical coincidences (sound is never used for really accurate measurements). We are therefore forced to postulate that light travels with a finite speed which is independent of the motion of the observer. Further, we must restrict this postulate to light, and accept that other speeds are affected by the motion of the observer . otherwise we would come into conflict with common experience Besides, the convection coefficient  $1-1/\mu^2$ , which gives the amount by which the speed of light in a medium like water (refractive index  $\mu$ ) is affected by the motion of the medium itself, is a direct proof that the fundamental speed which remains unaffected by the motion of the observer is indeed the rate at which light travels in a vacuum.

Another difficulty that has been mentioned is the following. According to relativity, apparently, if an interval of time is measured by two observers A and B, then the value obtained by A will bear to the value obtained by B the ratio  $(1-v^2/c^2)^{-\frac{1}{2}}$ , where v is the velocity of B relative to A. But the velocity of A relative to B is -v, so that the value obtained by B should also be  $(1-v^2/c^2)^{-\frac{1}{2}}$  times the value obtained by A. This sounds absurd, and is reminiscent of the rather tantalising game with paradoxes that exponents of relativity used to include in before admiring and bewildered audiences. But consider the facts carefully.

The Lorentz transformation is:

$$x' = \frac{x - vt}{(1 - v^2/c^2)^{\frac{1}{2}}}, \quad y' = y, \quad z' = z, \quad t' = \frac{t - vx/c^2}{(1 - v^2/c^2)^{\frac{1}{2}}},$$

where (x, y, z, t) refer to A, and (x', y', z', t') to B, the direction of the relative motion being along the x, x' axes. Hence we get

$$\begin{split} \Delta t' &= \frac{\Delta t - v/c^2 \cdot \Delta x}{(1 - v^2/c^2)^{\frac{1}{2}}}, \\ \frac{dt'}{dt} &= \frac{1 - v/c^2 \cdot dx/dt}{(1 - v^2/c^2)^{\frac{1}{2}}}. \end{split}$$

The ratio of the intervals dt, dt' thus depends also on dx/dt. If dx/dt is zero, we get  $dt'/dt = (1 - v^2/c^2)^{-\frac{1}{2}}$ . But now let dx/dt = v; then  $dt'/dt = (1 - v^2/c^2)^{\frac{1}{2}}$ . Whereas in the first case we measure an interval between events at a place fixed relative to A, we are in the second case measuring an interval between events at a place fixed relative to B. There is no inconsistency; the results are in fact consistent and logically correct.

A further difficulty arises in a similar way. If B have velocity v relative to A, then both x' and t' in terms of x and t have the same factor  $(1-v^2/c^2)^{\frac{1}{2}}$  in their denominators. Hence it would seem that

any velocity ought to appear the same to both A and B!

The fallacy lies in arguing from

$$x' = (x - vt)/(1 - v^2/c^2)^{\frac{1}{2}}$$

with t = 0, and from

$$t' = (t - vx/c^2)/(1 - v^2/c^2)^{\frac{1}{2}}$$

with x=0, and then applying the two results, obtained for different conditions, to a velocity, in which the length and the time refer to the same conditions. The correct procedure is thus:

$$\frac{dx'}{dt'} = \frac{dx - vdt}{(1 - v^2/c^2)^{\frac{1}{2}}} \bigg/ \frac{dt - vdx/c^2}{(1 - v^2/c^2)^{\frac{1}{2}}}$$

$$= \frac{dx - vdt}{dt - vdx/c^2} = \frac{dx/dt - v}{1 - v/c^2 - dx/dt}.$$

In order to get dx'/dt' = dx/dt we must have

$$\frac{dx}{dt}\Big(1 - \frac{v}{c^2}\frac{dx}{dt}\Big) = \frac{dx}{dt} - v$$

which leads to (i) v=0 or (ii)  $dx/dt=\pm c$ . (1) is trivial; (ii) means that only the speed of light is the same to both observers.

In the general theory of relativity very few persons attempt to follow the reasoning that establishes the equations of the gravitational field, and most people are prepared to take for granted the definition of  $ds^2$  in terms of the differentials of the four space-time co-ordinates. Where they begin to see 'physical' arguments is in connexion with the statement that the path of a particle of very small mass must be a 'geodesic' in the space-time continuum thus defined. The following difficulty has been raised: "It is said that the nearest way from any place to any other place on the earth is by following a geodesic. Surely this is not the case, for the nearest way is through a tunnel cut in a straight line."

It is an unfortunate fact that the best examples of geodesics are in connexion with curves on surfaces. These examples are therefore invoked in order to bring nearer to the minds of laymen the notion of geodesics in general. The effect is seen in the puzzle just quoted, and in the conclusion reached by the questioner: "Einstein's idea of space seems to be that which a fly might have walking round inside a glass globe."

When we talk about a geodesic on a surface, then we postulate a being that is restricted to moving about on the surface, and is physically and constitutionally incapable of getting away from the surface. The being may have intellectual knowledge of points off the surface, but such points are outside its physical or dynamical ken. Thus a tunnel through the earth is simply irrelevant to the question of geodesics on its surface. This is in actual agreement with life, as tunnels which are of such a length as to produce shortening of the path relative to the geoid are outside the domain of the practical, and all tunnels in use are constructed for the purpose of keeping as close as possible to the geoid and realising the geodesics on it.

Simplification, however, does not always lead to intelligibility, and it is doubtful whether the non-mathematical student of relativity is well advised to envisage geodesics on a surface, in order to understand geodesics in the four-dimensional space-time continuum. Consider rather geodesics in three dimensions in the following sense. In modern practical life time is often more important than distance, the former being endowed with an economic cash value denied to the latter. If A, B are two points in space, how can one go from A to B in the shortest possible time  ${}^{?}$  If the space is empty, and there are no aids or hindrances in the form of accelerative forces or resistances, intuition tells us that the geodesic (in the time sense) is what we ordinarily call the straight line joining A to B in empty Euclidean space. But now suppose that the space contains aids and hindrances to the motion. Suppose, for example, that between A and B there is a slab of matter through which the motion is necessarily slower than in the empty space. Then one needs no mathematics to see that unless the slab has plane parallel faces perpendicular to the line AB, the geodesic is not the straight line AB. The path of a ray of light in passing obliquely through a thick plate of glass is a relevant and clear example Still more striking is the path of a ray through a prism. The time taken by the light in travelling between two points, one on each side of the plate or prism, is less than what would be required for any other path between these points, and deviating only slightly from the actual path.

The advantage of considering geodesics in three dimensions is two-fold. In the first place there are no 'tunnels' to distract attention. In the second place it is not very difficult now to conceive that the four-dimensional space-time continuum has varying properties from place to place, so that a geodesic would not in general be straight as understood in the empty space of Euclid. The path of a particle would thus be curved, as viewed from the standpoint of empty Euclidean space, and it is not difficult to see that the natural paths may be, say, circular or elliptical, or in accordance with the more complicated results of

the general theory of relativity.

This brings us to the last difficulty which we shall discuss here: it is in connexion with the bending of light rays which are affected by the sun's gravitational field, or rather by the properties of the space-time continuum in the neighbourhood of the sun. Can this not be attributed simply to the attraction exerted by the sun on the light since we now know light to have both corpuscular and wave properties? It has been argued that even if the observed deflexion is found to be double that given by Newton's law of gravitation in accordance with classical mechanics, yet one might "doubt whether such a calculation is possible until we know the size and mass of the corpuscular element of light with the same degree of accuracy as we know the size and mass of electrons."

The fact is, of course, that the deflexion that would be obtained on the basis of the Newtonian

theory is quite independent of the size and mass of the hypothetical corpuscular element of light One might indeed invent some modification of the classical Newtonian theory so as to obtain the observed deflexion. But there is surely no point in postulating a theory which does not exist, in order to avoid accepting a theory which sums up in a remarkable manner so many of the laws and phenomena of mechanics, astronomy, and optics.

We all love sensations, and recently a prominent daily newspaper published a column about an alleged forestalling of Einstein by a German astronomer, who a century ago calculated the deviation of a ray of light on the basis of Newton's law of gravitation and the corpuscular theory of light. The formula there given is actually a correct deduction from the inverse square law, but when it is worked out numerically the result is just half of Einstein's value, and of the average value obtained at the eclipses in recent years. The relativity theory of gravitation not only 'explains' gravitation in the sense of representing it as a deduction from reasonable views of the space-time continuum, giving as a first approximation the Newtonian inverse square law, but also yields just the correction required to account for the observed motion of Mercury, and further gives a deflexion of light rays passing near the sun in agreement with observed fact.

# Obituary.

#### MR A. D MICHAEL.

THE debt which natural science owes to the work of amateur microscopists has often been commented on. Not a few names of weight in systematic zoology are those of men who turned a fascinating hobby into a serious study, and by patient and prolonged observation acquired a familiarity with the living creatures that the professional zoologists often have cause to admire and envy.

Of this type was Mr. A. D. Michael, well known as an authority on the mites (Acarina), whose death at an advanced age was recently reported. Not only did he produce admirable systematic monographs on several families of the group, but also he was successful in unravelling many details of their often complicated and puzzling lifehistories. Together with his wife, who assisted in all his researches, he acquired remarkable skill in minute dissection, and his accounts of the internal anatomy of many forms will not soon be superseded. One of his most interesting discoveries concerned the forms known by the name Hypopus, which are minute, hard-shelled mites with vestigial mouthparts, found attached to various winged insects by Their nature had been the means of suckers subject of a great deal of discussion, but by patient observation and experiment Michael was able to show conclusively that the Hypopus is an alternative developmental stage in the life-history of various Tyroglyphidæ (the family which includes the cheese-mite) adapted to secure the dispersal of the species.

Mr Michael was born in London in 1836. He was educated at King's College, London, and became a solicitor, succeeding to his father's practice. He seems to have taken up microscopy shortly after his marriage in 1865, but his first published paper on the Acari appeared in 1878 His later publications, some fifty in number, appeared mainly in the Journal of the Royal Microscopical Society, the Journal and the Transactions of the Linnean Society, and the Journal of the Quekett Club. Nearly all of these were finely illustrated by his own pencil, as were also his monographs of the British Oribatidæ (2 vols., 1883, 1888) and British

Tyroglyphidæ (2 vols, 1901, 1903) published by the Ray Society. In 1898, he contributed a revision of the Oribatidæ of the world to "Das Tierreich." He was in succession president of the Quekett Microscopical Club (1885–87) and of the Royal Microscopical Society (1893–96), and vice-president of the Linnean Society (1896–1900). Shortly before his death he presented his large collection of finely prepared microscopic slides of Acari to the British Museum (Natural History) and his microscopes to the Royal Microscopical Society. He died in a nursing home at Bournemouth on June 16 last W. T. C.

An appreciation by C. Hart Merriam in Science of April 8, of Dr William Henry Dall, reminds us that by the death of this veteran conchologist on Mar 27 last, zoology is deprived of one of the last remaining naturalists of the old school. Although chiefly known as a student of the Mollusca, Dr. Dall's activities were by no means confined to this group, his papers and monographs on a variety of subjects all ranking high in scientific literature His earlier work was chiefly on the natural history of Alaska, which he visited as one of the scientific staff, and later as head, of the Western Union International Telegraph Expedition. Besides exploring and mapping much of the Yukon River, he found time for observations on birds, fishes, and whales, the results of which, as well as geographical works on Alaska, were all published before 1880. From 1871 until 1874, Dr. Dall was surveying the Aleutian Islands and adjacent coasts; from 1880 until his death he was honorary curator in the National Museum, and palæontologist of the United States Geological Survey from 1884 until 1925. From 1893 until 1927 he held the chair of invertebrate palæontology in the Wagner Institute of Science, from 1899 until 1915 was honorary curator of the Bishop Museum, Hawaii, and m 1899 again visited Ālaska with the Harriman Alaska Expedition as one of the scientific guests. Dr. Dall's unique experiences thus render his works peculiarly valuable, whether he is remembered as a zoologist, palæontologist, or explorer.

# News and Views.

The appointment is announced in the London Gazette of a Royal Commission on Museums and Galleries under State control in London and Edinburgh. The announcement is a welcome indication of the interest of the Government in the great national collections for which it is responsible. For many years the majority of the twenty institutions named in the terms of reference has each pursued its own course unhampered by consideration of the development of sister institutions, and now the promise arises of a means of unifying efforts and correlating activities, which cannot but result in benefit to the institutions themselves and particularly to the public which supports and makes use of them. The need for such an investigation has recently been strongly urged in NATURE by Sir Ray Lankester, and also in a leading article in our issue of April 16 The Commission is a strong one Every member has had wide administrative experience: finance is specially represented by the Lord D'Abernon (chairman) and Sir Thomas Heath: artistic interests by the chairman, Mr. Evan Charteris, Sir Martin Conway, and Sir Robert Witt; education and the libraries by Sir George Macdonald and Dr. A. E. Cowley; the buildings in which the properties are housed by Sir Lionel Earle; and science by Sir Richard Glazebrook and Sir Henry Miers, the last of whom was himself at one time an assistant in the British Museum (Natural History). It is unfortunate that the Commission includes no one intimately qualified to weigh the evidence from the biological sciences, although they must occupy a large part of the inquiry, since they cover most of the Natural History Museum at South Kensington, the Royal Botanic Gardens at Kew, a large section of the Royal Scottish Museum, and the Royal Botanic Garden in Edinburgh, the name of which, surely by some slip, does not appear in the terms of reference.

IT is interesting to notice that in this official announcement the present clumsy title of the "British Museum (Natural History)" is simply replaced by "Natural History Museum"—a change long since advocated in these pages. The terms of reference are of the widest character. They include an inquiry into the legal position, organisation, administration, accommodation, and structural condition of the buildings and general cost of the institutions; an investigation of the past growth of the collections and estimate of the probable growth in the next half-century. Consideration is to be made of possible means of lightening the financial burden upon the taxpayer, either by curtailing expenditure or by instituting a more general system of entrance fees The questions of duplicate specimens and their distribution by sale or loan to provincial museums; of better correlation between the exhibits of the State institutions; of hampering conditions attached to benefactor's bequests and the possibility of their removal or modification, are all specified as part of this comprehensive inquiry. An exceedingly important clause, which may well lead

to a turning-point in the history of British national museums and gallenes, reads. "to consider whether the existing administrative responsibility for the various institutions is the most appropriate under modern conditions and whether it conduces to the most advantageous distribution and display of the national treasures, and to report whether it would be desirable, while preserving certain defined powers to their Trustees or Directors, to place them all under some central authority or under different authorities than those at present controlling them." The terms of reference treat the national collections as educational units isolated from and independent of the rest of the educational system of the country. The position is a mistaken one; it is to be regretted that no hint is given of a desire to bring museum and art collections into active and responsible connexion with the great teaching institutions which lie outside the control of the State.

The King of Spain has presented to the Natural History Museum, South Kensington, a group of Spanish ibex (Capra pyrenaica victoriæ) from Sierra de Gredos, Avila, Spain. It is a new race which was named by Prof. A. Cabrera after the Queen of Spain. The group, which consists of a male, female, and young, was mounted and realistically arranged in its natural rocky surroundings by Senor Lius Benedito, of Madrid. and the case containing it has been placed in the Central Hall, immediately facing the entrance. These specimens are the first of the race to be received at the Museum and form a valuable accession to the collections. The male and the young one were shot by the King on his estates. The race was a few years ago in danger of extinction, but, thanks to the King's active efforts to preserve it, its numbers have now increased to many hundreds. At the presentation, which was made by King Alfonso on July 7, King George was also present, and their Majesties were received by four of the Trustees—the Archbishop of Canterbury, the Earl of Crawford and Balcarres, Lord Rothschild, and Mr. F. Cavendish Bentinck—and by Sir Frederick Kenyon, Dr. W. T. Calman, Major E. E. Austen, Dr. W. D. Lang, Dr. G. T. Prior, Dr. A. B Rendle, and Dr. G. F. Herbert Smith. The Spanish Ambassador and the Duke of Miranda were also present.

ELSEWHERE in this issue a communication from Mr. L. S. B. Leaky deals with the discoveries relating to early man in Kenya Colony, to which reference was made in Nature of Jan. 8 last. Mr. Leaky's more detailed account fully confirms the importance of this discovery, although for the moment, pending a detailed examination of the implements, pottery, and skeletal remains, and a closer acquaintance with the conditions of the finds, judgment as to its full significance must remain in suspense. It is obvious, however, that this fresh evidence of early man in East Africa presents some very striking features. Particularly interesting is the addition to the sites outside Europe upon which

a microlithic industry has been found, especially if Mr. Leaky's contention that it is mesolithic can be sustained. Features of the skeletal remains with which this industry is associated mark it off most emphatically as the culture of a race quite distinct from any of the present or of the known recent inhabitants of the country Reference to the illustrations will confirm the distinctive character of certain features which Mr Leaky describes, especially the remarkable character of the Nakuru mandible with its high ascending ramus and the long and narrow non-negroid nose of the Elmenteita people. We regret that in our previous note, as pointed out by Mr. Leaky, it was inadvertently stated that his previous archæological investigations had been carried out in Uganda instead of Kenya, and that it was not made clear that his present expedition had no relation to the previous expedition of which he was a member.

FIFTY years ago a significant event occurred in the history of the human race, whether regarded from the biological or the sociological point of view-the trial of Charles Bradlaugh and Mrs Annie Besant for republishing Dr. Charles Knowlton's pamphlet "Fruits of Philosophy," in which principles and methods of what are now called birth-control were described. From that trial sprang the neo-Malthusian or birthcontrol movement; the Malthusian League having been formed on July 26, 1877, followed by leagues in Holland, Germany, France, and several other European countries, and culminating in the American movement pioneered by Dr. W. J. Robinson and Mrs. Margaret Sanger. The interest evoked by the trial was so great that hundreds of thousands of copies and translations of the Knowlton pamphlet, of Dr. George Drysdale's "Elements of Social Science," and other booklets were sold within the next few years, and the birth-rate of England and several other countries, which had been rising before the trial, showed a more or less strong downward tendency from that year. Man had already begun to apply science to master most of the external forces of Nature, but he was still subject to the law of the struggle for existence due to excessive reproduction; and the year 1877 opened up a new era of man's control over his own destiny by the substitution of rational for natural selection. The Malthusian League will celebrate the jubilee of the Knowlton trial and of its own formation by a dinner at the Holborn Restaurant on July 26, at which Prof. J. M. Keynes will preside, and the speakers will be Dr. Annie Besant, Mr. H. G. Wells, Dr. C. V. Drysdale, and Mr. J. Sumner. Particulars can be obtained from the Secretary of the League, 120 Victoria Street, S.W.1.

There were at one time few British men of science more widely known than Sir Frederick Abel, the famous chemist, the centenary of whose birth falls on July 17 of this year. All his life Abel was associated with notable men and institutions. One of the twenty-six original students of the Royal College of Chemistry, he was made one of Hofmann's assistants and became the successor of Faraday at the Royal

Military Academy, Woolwich. This appointment determined his career and most of his original work related to explosives. He collaborated with Dewar and with Noble, and with Dewar was the inventor of cordite. His standing was such that at various times he was president of the Chemical Society, of the Institution of Electrical Engineers, of the Iron and Steel Institute, and of the British Association. Neither did his public services end here, for on his retirement as Chemist to the War Office he was made chairman of the General Committee on Explosives, and for several years was Secretary and Director of the Imperial Institute. He took a leading part in promoting the testimonial to Hofmann in 1888 and delivered one of the Hofmann Memorial Lectures to the Chemical Society. Abel died on Sept. 6, 1902.

An interesting development in the financing of mdustrial research has recently taken place in Australia. For many years tobacco has been grown in various districts, but for the most part the colour and aroma have been unsatisfactory, comparing most unfavourably with Virginian leaf A leading tobacco manufacturing company in the Commonwealth, The British-Australasian Tobacco Co, Pty. Ltd., has incorporated as much of the local leaf in its products as its customers will accept, and has made considerable effort. without much success, to discover the reasons for its inferiority. It has now offered to provide £20,000 towards the cost of a thorough scientific investigation of the whole problem of tobacco-growing, on condition that the Commonwealth and State Governments provide £10,000. If, when this sum is exhausted, the results obtained appear to justify it, the Company will give an additional £30,000 if the Governments will give a like sum. Thus altogether £90,000 will be available for the investigation.

THE Commonwealth Government has accepted this generous offer, and the executive control of the work is to be handed to a committee of three members. Mr. H. W. Gepp (chairman of the Development and Migration Commission), Dr. A. C. D. Rivett (chief executive officer of the Council for Scientific and Industrial Research), and a third member to be nominated by them, who will probably be Dr. Darnell Smith of the N S.W. Department of Agriculture. Dr. Smith has recently completed some very successful work on the control of blue mould in tobacco plants. The services of experts in tobacco growing both in the Commonwealth and abroad will be sought, but it is expected that many years of work will be required before the problem of growing first-class Australian leaf is solved. This is one of the first instances of a business organisation placing large funds for the investigation of a national problem in which it is interested at the disposal of government institutions. and it is to be noted that the Company has deliberately refrained from seeking any measure of control of the work or of the expenditure upon it.

Several interesting photographs of the eclipse of the sun on June 29, including the picture reproduced in Nature of July 9, were shown at the meeting of the British Astronomical Association on July 6. Among the lantern shdes exhibited were some striking photographs of the corona taken at Giggleswick by Dr. R. L. Waterfield. One of these is here reproduced (Fig. 1) with the disc entarged to double its diameter on the original negative. This picture was obtained with a Wray visual lens of 4-in, aperture and 60-in, focal length. A super-speed panchromatic plate (reputed speed, 1250), kindly prepared and provided by the Imperial Dry Plate Co., was used, and the exposure was just under one second. Five

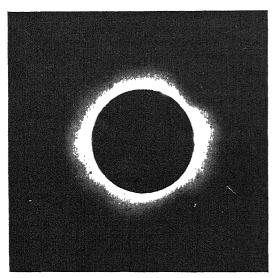

FIG 1 —Photograph of solar corona, taken at Giggleswick on June 20 by Dr. R. L. Waterfield  $\times 2$ . Exposure 1 sec

inches in front of the plate a Beta (Ilford) filter was placed, and this, by cutting out both the blue and red ends of the spectrum, corrected the visual lens and avoided sky scattering. The exposure factor of the filter was 3; hence the effective focal ratio was increased from f 15 to f 45. A large part of the extent, and much of the fine detail, has, of course, been lost in the process of reproduction, so that the accompanying illustration does not do justice to Dr. Waterfield's beautiful picture. We understand, however, that lantern slides are being prepared by Messrs. Hamblin, Ltd., 15 Wigmore Street, London, W.1, and will shortly be on sale.

COMMANDER R. E. BYRD, who recently flew the Atlantic and last year flew from Spitsbergen to the Pole and back, proposes to lead an expedition to the Antarctic leaving America in the autumn According to the Times his base of operations will be on the edge of the Ross Barrier and the purpose of the expedition will be scientific exploration of Antarctica. The expedition will number about fifty men and will take two aeroplanes in addition to dogs and sledges. The aeroplanes are to be provided with floats interchangeable with skis. One of the machines will be three engined and used for a flight to the Pole. The other smaller machine, with one engine, is to be employed in reconnaissance work. Commander Byrd

is reported to have expressed his belief in the existence of a large area in the continent not covered by snow. Enough is known of Antarctica to make it possible to deny the probability of this. At the same time, if landing-places prove suitable, some useful general work might be done by aeroplane, particularly to the south and east of Edward Land. In the autumn a projected Argentine expedition has already announced its plans of flying from Graham Land to Victoria Land.

The terrible floods which have recently occurred in the Lower Mississippi Valley have been taken as the text for an article issued by Science Service of Washington on the ancient issue of forests versus engineering works as means of preventing floods. America lacks any results based on actual scientific experimental work in this direction. But it is pointed out that the older countries of the world have spent long years (the word might have been centuries) in the hard school of adversity and in acquiring experience in this matter and have learnt many lessons France, Italy, Switzerland, and Spain have suffered severely in the past through the disafforestation in mountainous regions of the catchment areas of the big rivers Large sums of money have been spent in Europe and much patient experimental work has been carried out to build up the knowledge and scientific data which are available at the present day. In dealing briefly with this matter, the writer points out that floods are not only detrunental, through the sheer weight and force of the water, to property, both house and land, as also a danger to life; but he shows that they carry along with them in their destructive path great quantities of the earth's most fertile soil, which fills up reservoirs and irrigation works, silts up rivers and streams, chokes harbours and forms bars across the mouths of previously navigable rivers. He instances America's danger owing to the unchecked lumbering of the forests which has for so long taken place; and concludes his note with the statement that expert opinion nowadays is unammous in making use of a combination of engineering methods and forestry to control floods, rightly saying that both foresters and engineers in Europe hold that the establishment of a forest cover is a very necessary step.

The new giant dirigible R100, which is being built at North Howden, Yorkshire, will have accommodation for a hundred passengers and a crew of lifty. The electrical equipment is being provided by the Metropolitan Vickers Electrical Company and presents novel features, as considerations of safety and the necessity of using the lightest possible material complicate the problem. It is necessary to use equipment of the least possible size and the highest efficiency. Two generators giving a total output of 25 kilowatts are to be installed in the machinery cars, where they will be driven by the small petrol engines used for starting the main driving engines of the airship. The casings and fittings throughout the ship will be made of light alloys. A cable having its conductor

and sheathing both of aluminium will be used. As the envelope has a capacity of five million cubic feet of gas, every precaution has to be taken to prevent open-air sparking due to any fault in the wiring. The sheathing of the cable, although it is strong, is capable of considerable extension. In the event of undue forces being applied to it, the conductor will break whilst the sheath is still intact, and thus an external spark will be prevented. The electrical system provides for compartment and navigation lighting, compartment heating, cooking, water heating, and radio signalling.

Radio beam communication has been making most satisfactory progress in Great Britain, mainly due to the ability of the engineers of the Marconi Company The beam systems connecting the Post Office directly with Canada and Australia are working well. The system connecting London and Cape Town is finished, and the last of the Imperial group of the radio beam stations connecting London and India will be inaugurated next month. In the original contract it was specified that communication with Cape Town should be maintained for at least eleven hours a day. Senatore Marconi found in 1924 that when the wavelengths transmitted were less than 100 metres. excellent communication could be maintained during the night time. He also found out that when the wave-length was lowered below 30 metres, daylight signals could be sent but night signals deteriorated. Further investigation showed that to Cape Town, wave-lengths of 33 metres were excellent during darkness and waves of 16 metres were equally excellent during daylight. By using two wave-lengths, therefore, they are able to maintain almost continuous service. The Marconi Company calculates that good traffic operation, high-speed duplex operation at speeds of more than 100 words per minute, can be maintained for about 22 hours per day outwards to Cape Town and about 20 hours a day inwards from South Africa. These results are as welcome as they are unexpected. This is the first station to use two wave-lengths, one for daylight and the other for night communication. It is particularly convenient that the standard time of the Union of South Africa is only two hours fast of Greenwich time. Sunset and sunrise therefore in both countries occur at nearly the same time. In the case of the Australian service, only one wave-length is used, but transmission takes place in one direction round the world during one portion of the 24 hours and in the opposite direction during the remainder of the time.

THE Institute of Physics gives notice that its examination of candidates for associateship will take place in London in September next. The latest date of entry for the examination is July 31. Forms of application can be obtained from the secretary, 1 Lowther Gardens, S.W.7.

RESEARCH Fellowships for work on textiles or any problem having a bearing on wool, in chemistry, engineering, physics, zoology, or other sciences, and Advanced Scholarships for those intending to enter the

woollen and worsted industries, are being offered by the British Research Association for the Woollen and Worsted Industries, particulars of which are obtainable from the Secretary, Torridon, Headingley, Leeds. The latest date for the receipt of applications is July 31.

The following have been elected honorary fellows of the Royal Society of Edinburgh: British Honorary Fellows—Sir William Bragg, Sir David Bruce, Sir J. B Farmer, Sii F G Hopkins. Foreign Honorary Fellows—Niels Bohr, professor of physics, University of Copenhagen; Jules Bordet, professor of bacteriology, University of Brussels; Albert Einstein, professor of mathematical physics, University of Berlin, Hans Horst Meyer, emeritus professor of pharmacology, University of Vienna, Johannes Schmidt, Carlsberg Laboratorium, Copenhagen, Richard Willstatter, professor of chemistry, University of Munich

A service of air liners for passengers and mails is being rapidly developed in America. Science Service of Washington gives details of several of the longer routes. A service between San Francisco and Chicago is now open and will be extended to New York in August. The transcontinental journey is timed to take 32 hours compared with about four days by rail. Other routes now working are between Boston and New York, Salt Lake City and Los Angeles, and Seattle and Los Angeles. The long-distance routes are now lighted for night traffic. On Aug. 1 the air mail routes will pass from government to private control, and most of the lines which now carry only mails will then cater for passengers also.

THE preliminary programme has been received of the fifth International Congress of Genetics, to be held in Berlin on Sept. 11-18. The presiding committee includes leading geneticists from various countries interested, and general addresses have already been arranged to be given by such wellknown workers as Wettstein, Rosenberg, Pearl, Federley, Vavilov, Pézard, Correns, Seiler, Crew, and Muller. English, French, and German are proposed as the official languages, and other languages may be admitted by action of the Congress. The membership fee is 15 Reichsmark, while the subscription price for a copy of the Proceedings of the Congress is fixed at 30 Reichsmark. Ladies accompanying members to the Congress pay no additional fee. Those intending to read papers before the Congress are asked to notify the Committee before Aug. 1. The Congress is divided into three sections: (1) General genetics and cytology. (2) Heredity in man and eugenics. (3) Animal and plant breeding. In addition to papers and demonstrations, excursions during and after the meetings are being arranged. Requests for further information should be addressed to Prof. Erwin Baur, Albrecht-Thaer-Weg 6, Berlin-Dahlem.

AT the recent meeting of the Trustees of the Beit Memorial Fellowships for Medical Research, Dr. H. H. Dale, head of the Department of Biochemistry and Pharmacology of the Medical Research Council, was appointed a member of the advisory board in succession to the late Prof. E H. Starling. The following elections to fellowships were made, the subject of research and value and term of the tellowship being indicated after the name - Senior Fellowship in Tropical Medicine (£1000 a year for five years). Dr. E Hindle—spirochætosis, with special reference to the causation of yellow fever. Junior Fellowship in Tropical Medicine: Dr H. P. Hacker-problems in the prevention of malaria Junior Fellowships (£400 a year): Dr. F. R Winton—the physiology and pharmacology of urmary secretion and the physiology of manunahan plain muscle, Mr. W. R. Wooldridge-bacterial chemistry and its application to immunological problems, Mr W T J. Morgan—the structure of the hexosephosphoric acids by the method of methylation and subsequent oxidation; Mr. P. Eggleton-the carbohydrate metabolism of contractile tissue and a comparative study of different types of contractile tissue; Mr G. F Marrian—the physiological rôle of vitamin B, and the chemistry and physiology of the adrenal glands; Mr. A. R. Fee—the oxygen usage of the kidney, with particular reference to the action of pituitrin, and the factors controlling the elimination of acids and alkalis by the kidney, by the isolated heart-lung-kidney preparation and other methods. Three appointments of Junior Fellows to Fourth-Year Fellowships and one appointment of a Fourth-Year Fellow to a Senior Fellowship were also made

APPLICATIONS are invited for the following appointments, on or before the dates mentioned .—A master for mechanical engineering subjects and mathematics at the Sheerness Technical Institute and Junior Technical School—The Puncipal, Technical Institute,

Assistant chemistry and en-Sheerness (July 18) gineering drawing and mathematics masters at the Junior Technical School, Smethwick—The Director of Education, 215 High Street, Smethwick (July 23). An assistant to the director of the Chineal Laboratory of the Manchester Royal Infirmary, with research experience in physical or organic chemistry or in biochemistry—The General Superintendent and Secretary, Royal Infirmary, Manchester (July 28). A principal of the Mansfield Technical College-The Director of Education, Shire Hall, Nottingham (July 30). Two research fellows in the Department of Glass Technology, The University, Sheffield—The Registrar, The University, Sheffield (Aug. 6). A student probationer (Aug. 13) and a technical laboratory assistant at the Millport Marine Station of the Scottish Marine Biological Association—The Secretary, Scottish Marine Biological Association, 88 Bath Street, Glasgow. A professor of chemistry in the University of Melbourne — The Agent - General for Victoria, Australia, Victoria House, Melbourne Place, Strand, W.C.2 (Oct. 1). A lecturer in mathematics at the Gordon College, Khartoum—The Controller, Sudan Government London Office, Wellington House, Buckingham Gate, S.W.1. An assistant lecturer in science at the Training College, Carmarthen-The Principal. An engineering workshop instructor at the Battersea Polytechnic-The Principal, Battersea Polytechnic, Battersea, S.W.11. A demonstrator of pathology in the University of Bristol-The Registrar. Two entomologists in the agricultural department of Kenya and two entomologists in the agricultural department of the Straits Settlements and the Federated Malay States - The Private Secretary (Appointments), Colonial Office, 38 Old Queen Street, S.W.1.

# Our Astronomical Column.

The Nautical Almanac for 1929 —A number of changes and additions in this issue of the "Nautical Almanac" call for comment. At the meeting of the International Astronomical Union at Cambridge in 1925, a resolution was adopted to the effect that the ephemerides should give 5-figure values of the logarithms of the quantities  $\rho \sin \phi'$  and  $\rho \cos \phi'$ , including the effect of altitude, for each observatory. This has already been done, and natural values as well as logarithms are given. The number of observatories listed has been more than doubled, while the list has been divided into two—active observatories and former observatories. A third or index list gives every conceivable cross-reference. The lists appear to be very complete, and it is stated that in each case the authority for the latitude and longitude is a reply sent by the observatory to a circular letter.

The list of Standard Times has been greatly extended, and Non-Standard Times added, so that two pages summarise the times adopted in every civilised country.

There is an addition which should be welcome to those who compute orbits of comets and asteroids. This is the sun's co-ordinates, both spherical and rectangular, for the equinox of 1950-0, for each midnight in 1928 and 1929. The longitude and latitude are given both to 0°-00001 and to 0"-1, and the natural radius vector (an invitation to calculating machines) to seven decimals; first differences are

printed throughout. The co-ordinates X,Y,Z are given to seven decimals as usual, but with first and second differences.

Two pages are devoted to interpolation tables, in the critical form, giving coefficients of the second, third, and fourth differences. It is believed that this is the first occasion on which the principle of critical tables has been applied to published interpolation tables. They can be recommended not only to astronomers, but also to all who have to deal with the art of interpolation.

The other features remain as in 1928. It is stated on page 667 that considerable changes are contemplated in the "Almanac" for 1931. The "Almanac" is available either in paper covers as formerly, or bound in cloth.

THE STONYHURST COLLEGE OBSERVATORY.—The Report of this observatory for 1926 is to hand. The solar disc was drawn on 281 days; the mean daily disc area of spots, in units of 1/5000 of the visible surface, was 5 33, as compared with 3 53 in 1925 and 1·36 in 1924. The activity was equally divided between the northern and southern hemispheres. The magnetic activity increased in sympathy with the spot activity. There were 31 per cont. 'quiet days' as compared with 36 in 1925. 32 earthquakes were recorded in 1926, 55 in 1925, and 106 in 1924.

# Research Items.

THE LAPCHAS.-Vol. 31, No. 4, of the Journal and Proceedings of the Asiatic Society of Bengal is a study of the folklore of the Lapchas of Sikhim, supplemented by incidental notes on their social anthropology, by Mrs. C. de Beauvoir Stocks, which is based upon observations made on two journeys in that country m 1925. Very little attention has been paid to the Lapchas and, owing to contact with Tibet—the Lapchas and, owing to contact with Tibet—the Sikhim Rajas are of Tibetan descent and are recognised as in a sense alien by the people-and India, and their conversion to Buddhism, their folklore shows extraneous influences, also perceptible in their customs and beliefs, but not always easy to disentangle in the present stage of our knowledge of them and their immediate neighbours among the Himalayan peoples. For example, the conceptions of gods is vague, and apparently it had not attained any advanced stage of development when it was superseded by Buddhism. It would appear that there were five derities, but even their names may have been forgotten as the terms at present applied to them m certain cases are purely descriptive, e.g. It-Mo, "The Ancient Mother," while others are of Tibetan origin. The five original deities are a family of mother, father, two children, and a son of the mother. Among them the creative power is attributed to the female deities. The mother is probably the living force of the animal and vegetable world. An especially significant figure is the Bong-thing, or medicine man, the son of a goddess who was sent as a Shaman to relieve human beings from the tortures of the demons. In Lapcha belief, as in Tibetan Buddhism, and in India, demons play a very prominent part, and the heroical tales are filled with demoniacal beings, ogres, etc., who haunt every locality which presents some dangerous or unusual character, such as the unhealthy jungle with its dangers from wild animals, or a hill-top, or cascade. One demon inhabiting the top of Mt. Tendong was said to take a toll of two lives in each year.

EGYPT OVER THE BORDER—Sir Flinders Petrie in Part II. of Ancient History for 1927 describes the results of his excavations in Palestine during the past winter. The site chosen for excavation was Tell Jemmeh, which has been conjectured to be the site of Gerar. It has fifty feet depth of runs, all dating from before the Roman period, whereas the "ruins of Umm Jerar," formerly identified with Gerar, are entirely of late Roman Age. The site is evidently, from the size of the ruined granaries, of importance as the centre of a great corn country. This fact, in conjunction with its position, explains much of the Genesis narrative. Four periods of construction so far have been examined: (1) The granaries, which belong to the latest occupation of the site in the fifth and fourth centuries B.C. These must have served as the base of the Persian army in maintaining the Persian hold on Egypt, for they are much larger than the needs of the inhabitants would require, being twenty and thirty feet across and probably thirty and fifty feet high. (11.) A fort similar to those of Naukratis with pottery of the seventh century B.C.; foundation deposits of model corn-rubber and calf bones marking it as of Egyptian origin. Scythian bronze and arrowheads were found around it as well as an iron arrowhead of the type found later in central Russia. (iii.) Chambers built without any regular plan with Cypriote pottery of the eighth and ninth centuries B.C. (iv.) Buildings of grand style built of great yellow bricks in a thoroughly Eygptian method of construction, which at latest can be assigned to the time of Shishak. Thirty feet of ruins still remain to be uncovered.

SPRAYING POTATOES.—Potato blight is a disease which attacks the haulms and foliage of the plant, and also causes the tubers to rot. In general it may be expected in Great Britain between mid-May and mid-June, though the time of its appearance varies in different parts of the country, usually being later in the north and drier eastern counties, for it is greatly encouraged by wet and mild conditions. Methods for the prevention and control of this disease are given in the Ministry of Agriculture's Leaflet No. 23. Bordeaux and Burgundy spray mixtures are especially recommended, successful results having been obtained since their first employment in 1885. Both contain copper sulphate, mixed with milk of lime and washing soda respectively, and full details of their preparation are given in the leaflet. The spray forms a gelatinous film over the surface of leaf and stem, acting as a protective rather than a remedy against the fungus, therefore spraying should preferably be done before the blight is detected. A second application after an interval of three or four weeks is recommended, and in wet summers a third may be needed. Dusting with powders is also used, but the results are not so satisfactory, as a less efficient film is formed. Further, the commercial article is liable to contain impurities, whereas the ingredients of the spray mixtures are readily obtained pure. Dusts are therefore not recommended except in cases where a shortage of labour or water occurs, though they are preferable to no action at all. The cost of one spraying is probably between 5s. and 7s. 6d per acre, 100-120 gallons of mixture being required; to this must be added the cost of labour. The increased value of the crop may on an average be reckoned as equivalent to the selling price of one to two tons per acre.

GREENHOUSE FUMICATION.—A number of pamphlets have recently come to hand dealing with greenhouse furnigation by means of calcium cyanide. With the expansion of the greenhouse industry there is an increasing demand for efficient fumigants. The old method of generating hydrocyanic acid gas by means of sodium cyanide or potassium cyanide and diluted sulphuric acid involves both trouble and some skill. Within the last two or three years calcium cyanide has been widely tested in the United States and placed on the market. In England this compound has also attracted some attention and a certain number of trials have been made According to Mr. H. W. Miles (Annals of Applied Biology, vol. 14, 1927, p. 240), for the majority of plants, routine fumigations require only one-quarter ounce of calcium cyanide per 1000 cubic feet of space to maintain a high degree of pest control. Its special advantages are the ease attending its use, since the powder is merely poured from its container into a measuring receptacle and distributed along the greenhouse paths, the house being then closed down and locked. On coming in contact with atmospheric moisture the calcium cyanide slowly evolves hydrocyanic acid gas. With the dosage mentioned it is stated that an area of 40,000 cubic feet can be furnigated at a cost of 1s. 8d. plus the cost of labour.

ACARINE DISEASE IN HIVE BEES.—Bulletin 33 (1927) of the North of Scotland College of Agriculture, by Dr. John Rennie, deals with the cause, nature, and control of Acarine disease in the hive bee. It is now tolerably well known that in this disease the thoracic breathing tubes of the bee are infested with mites which pass their whole existence in that situation. These mites are true parasites belonging to the family Tarsonemidæ and to the species Acarapis woodi

Rennie. Worker, drone, and queen bees are all liable to infection and, when the mites become securely established, affected bees eventually become disabled. This is primarily due to the continuous loss of blood, which the mites absorb through their piercing mouth-There is, further, a blocking of the air-tubes by the mites, which thus restricts the oxygen supply of the bee and causes a deterioration of the tissues connected with the infested parts. Weakened bees may work for a long time, but finally become unable to fly or to share in the normal life of the colony: the larvæ or brood of the bee, however, are never infested. The difficult subject of treatment of the disease is discussed at length. With slight infestations and with a stock numerically strong in autumn, there is a possibility of survival In cases of this kind where the percentage of intested bees in a random sample is about 30 per cent. or less, treatment of the hive with a mixture of chloropicrin, camphor, and methyl salicylate in minute doses is advised. This mixture, it is claimed, kills the parasitic mites without seriously interfering with the bees. Stocks badly infested in autumn or spring are useless; they merely function as sources of infection and are best destroyed. In cases of summer infection, treatment with volatile substances is not expedient, and success in such cases rather lies in management, so that the maximum of young foraging bees is produced at the time of honey flow. This is best effected by the early introduction of young queens, which produce bees faster than the disease can destroy them. Stocks thus saved, even though only temporarily, can be maintained for a time, at least, with profit.

SALMON OF THE OUTER HEBRIDES.-We have for the first time information on the salmon of the Grimersta District, Lewis, as a result of examination of scale measurements and other details obtained by Mr. W. J. M. Menzies (Fisheries, Scotland, Salmon Fish., 1926, 6 (January 1927)). A total of 803 fish taken on rod and line in 1925 are dealt with. Of these fish, 80 per cent. were grilse, the remainder being mostly 2 and 2+ winters fish. Compared with east-coast districts the scarcity of small summer fish was marked. The grilse were mostly taken in July, August, and September, 57.3 per cent. of the whole season's catch of grilse occurring in July. Previously spawned fish were only slightly more numerous than in the steadily netted districts of the east coast. average smolt age was considerably higher than in most other east-coast districts, 60 per cent. migrating in their third year; this is perhaps to be correlated with the scanty food supply available in the waters, which are surrounded by infertile, peaty and rocky country. One-year smolts were entirely absent, and 5 per cent. of the parr stayed in the fresh water for four or even five years before migrating The grilse four or even five years before migrating were a pound heavier and nearly two inches longer, on the average, than those from the Dee and Spey, but it is to be remembered that in the Grimersta district they run later than they do on the east coast, which possibly gives more time for feeding and growing. The scale erosion on the grilse begins in July, that is, very soon after cessation of feeding, the percentages with eroded, or, rather, absorbed, scales being 49.2 per cent. in July, 99 1 per cent. in August, and 100 per cent. in September. A check in growth was also noticed on the grilse scales, occurring apparently at about the same time as is the case for east-coast fish.

NATURAL PLANT HYBRIDS.—Numerous natural hybrids have been recognised in the flora of New Zealand, and Mr. H. H. Allan has recently described several of these hybrid swarms in a series of short

papers in Genetica (vols. 7 and 8). Some of the hybrid forms have been produced artificially by crossing. Coprosma Cunninghamii, which was described by Sir Joseph Hooker as an extremely variable species, is found to occur wherever C. robusta and C. propingua grow together. An artificial cross of these species produced a uniform F<sub>1</sub> closely resembling some forms of the wild C Cunninghamir. Melicope simplex  $\times M$ . ternata gives a series of wild forms which are believed to be partly the result of epharmonic response by the individual to wind-swept conditions and partly the sorting out of suitable forms by the diverse conditions. Other apparent wild hybrid swarms are Nothopanax anomalum  $\times$  N. simplex, Hoheria augustifolia  $\times$  H. sexitylosa and Corokia buddleoides  $\times$  C. Cotonicuster. A hybrid community of Hebe (the shrubby Veronicas) is more fully studied in conjunction with Messrs. G. Simpson and J. S. Thomson. The Hebes at Blanket Bay are found to show a mingling in various degrees of the characters of H elliptica and H, salicifolia var. communis, which are also found in the community. The conditions indicate a freely intercrossing population of forms in areas where both species occur; and the same is believed to apply to various other pairs of species of Hebe as well as other genera results will be further elucidated by crossing experiments which are being undertaken

CURRENTS OF THE ENGLISH CHANNEL.—Mr. J. N Carruthers (Jour. Marine Biol. Assoc, vol. 14, No. 3, March 1927, pp. 685-721) reports on an experiment with drift bottles, both surface and bottom, carried out by the Ministry of Agriculture and Fisheries and the Marine Biological Association jointly in July 1924. The bottles were liberated at the International Stations E2 and E3, and on the steamship route Southampton-St. Malo Of the surface bottles, those which did not run ashore on the Channel coasts were carried rapidly up Channel into the North Sea and across to the Dutch and Scandmavian shores. Many reached the Skaggerak, some 700 miles away, travel-Img at an average rate of 6 miles a day or more. During the period covered by the experiment there was an almost unbroken prevalence of south-westerly It cannot of course be inferred from these results that the water mass as a whole moved with the velocity indicated, and further experiments with wellsubmerged drifters would be valuable and interesting. The results have, however, enabled Mr. Carruthers to work out a relation between velocity of wind and surface current which corresponds closely with that found by R. Witting in the Baltic. The information yielded by the bottom bottles is summed up by Mr. Carruthers as follows: "There seems to be in Long. 2° W. (approximately) a parting of the ways in respect of the movements of the bottom water. To the north of 50° N. Lat. there appears to be a west-going bottom set, whereas to the south of this parallel there is a set in an easterly direction.'

Speed of Light in Moving Bodies —In the tenth volume of the Archives Néerlandaises des Sciences Exactes, Prof. P. Zeeman has collected together the work done by himself and his colleagues to determine the fraction of the speed of a moving body through which light is passing, which must be added to the normal speed of light to give the actual speed of the light. According to Fresnel, this fraction should be  $1-1/\mu^2$ , where  $\mu$  is the refractive index of the material for the light used. According to Lorentz, this fraction should be increased by  $(-\lambda/\mu)d\mu/d\lambda$  where  $\lambda$  is the wave-length. The measurements were made on water flowing through pipes and on quartz and flint-glass rods to which a to-and-fro motion was given by means of a revolving crank and connecting rod. The method

used was in principle that of the Michelson interferometer. The results agree with the formula of Lorentz

THE POSITIVE COLUMN OF GEISSLER DISCHARGES -Prof Guntherschulze has recently published the results of an extended series of measurements made by him on the electric fields present in a uniform positive column The point on which he lays particular stress is that the mean free path, rather than the pressure, is the relevant variable, and that it is therefore necessary to take into account the temperature of the ionised gas, which can be calculated in the way proposed many years ago by Warburg. With this precaution, the results of his measurements are fairly well expressed by two semi-empirical formula. For polyatomic gases the potential gradient is determined by the mean free path and by the diameter of the tube, and is practically independent of the current density for monatomic gases the gradient is independent of the mean free path (and hence of the pressure), but is a function of both the current and the size of the tube The processes of ionisation and conduction in a discharge-tube are still imperfectly understood, in spite of much recent work on the subject, but the data in these papers (Zeitschrift fur Physik, 41, p. 718, and 42, p. 763) provide valuable material for future theoretical development.

THE X-RAY INVESTIGATION OF INDIA-RUBBER.-In the *Chemiker-Zeitung* for May 21 is an account of two lectures by Dr J. R. Katz of Amsterdam on the application of X-ray analysis to the structure of india-rubber. So far, rubber in the unstretched condition has yielded very little information beyond the production of an 'amorphous ring spectrum,' similar to that obtained from liquids Recent work by the author appears to substantiate the hypothesis put forward by him in 1925 that rubber changes on stretching from an amorphous to a crystalline condition, the degree of change depending upon the extension. X-ray examination has revealed indications of a three-dimensional orientation of molecules, undiscernible in the unstretched material, although some of it still remains amorphous, as shown by the unchanged diameter of the 'amorphous ring' of the spectrum Moreover, there is a critical extension, below which the phenomenon is not observed. The conflicting results of W. H. Keesom's attempt in 1922 to apply a modification of Bragg's formula—which was specially designed for crystals-to calculate the mean distance of adjacent molecules (to a first approximation) in a liquid from the diameters of these rings, have now been shown to be due to the fact that the molecules were always assumed to be approximately spherical. This assumption is of This assumption is of course only applicable in certain cases, and it is now shown that the abnormal values were due to marked deviations in molecular structure from the spherical shape. The experiments of Katz appear to open a new and promising field of research.

HELIUM IN CANADA.—A comparatively new use of helium, and one that promises to become of very great importance, is its utilisation in the production of artificial atmospheres under which divers and caisson workers carry out their operations. It is anticipated that such atmospheres will permit of much greater depths being reached under water, longer periods being spent without fatigue, and, in the case of tunnel and caisson workers, that the prevention of what is known as 'caisson disease' will be facilitated. Investigations along these lines are being carried out by the United States Bureau of Mines, and accordingly considerable impetus has been given to the helium industry, which thus has other outlets besides that

of supplying airships with non-inflammable gas Canadian Mines Branch, during the period 1922 to 1926, made a special study of the helium-content of natural gas occurring within the Dominion, and the results of this investigation are now available in a report under the above title by Dr. R. T. Elworthy (No 679 Ottawa F A Acland 20 cents) significant that Canada is the only source of helium in the British Empire The report summarises our knowledge of this gas and is particularly valuable for its account of modern methods of recovery, it includes details of the varied helium-bearing gases (with analyses) in the Dominion and much interesting experimental data The most important source of supply of this substance discovered is in the natural gas from three small wells at Inglewood, Ontano, which yields as high a percentage of helium as that forming the basis of commercial operations at the well-known plant at Fort Worth, Texas; leases have been taken up by the Ontario Government in the Inglewood district, and it is anticipated that the National Research Council will lay down an experimental helium extraction plant, providing sufficient gas is available. The natural gas of Alberta, with the exception of Bow Island and Foremost fields, contains little or no helium, which, in view of these enormous resources, is unfortunate. However, if only 0 2 per cent. helium-bearing gas could be treated economically, it is believed that the Dominion could supply about 5,000,000 cubic feet annually.

Iron and Steel in India.—A paper by Richard Mather published in the Journal of the Royal Society of Arts, May 13, reveals the rapid advances which have been made during the last twenty years or so in the ferrous industries of India. Although Indian Wootz steel has deservedly possessed the highest reputation for quality for hundreds of years, it has only been during the last decade or two that the mitial difficulties associated with the establishment of a heavy iron and steel trade there have been overcome. Now, however, a large portion of the existing Indian demand is satisfied by Indian products, and also a surplus is available for export. This applies to pig-iron rather than steel, and the growth in the exports of this material during the last few years are as follows:

Year		7	Cons of pig-tron exported
1923			181,500
1924			271,000
1925			402,000
1926			315,000

In 1926, Japan took 75 per cent. of this iron and the United States 13 per cent In the former country Indian iron has become a serious competitor with the home product. With regard to steel, Indian production in 1911 was 10,000 tons, last year it was 540,000 tons, and it will probably exceed 600,000 tons in the present one. So far as future developments are concerned, Mr. Mather states that "the conclusion may safely be drawn that the Indian steel industry will develop, perhaps fairly rapidly, during the next few years, and that for some time afterwards its growth will depend mainly on the rate at which the demand increases. But for the next few years imports will not diminish to a great extent, unless the consumption declines or remains stationary; and even in later years there will remain an important market in India for certain kinds of steel " As an example of the value of this industry during the War, it was pointed out in the discussion that the military railways by which the Mesopotamian campaign was carried on, and even the line by which Lord Allenby made his successful attack on Palestine, were constructed of steel from the Tata works.

# National Physical Laboratory, Teddington.

INSPECTION BY THE GENERAL BOARD.

ON Friday, June 24, the General Board of the National Physical Laboratory made its annual inspection of the laboratory. A large number of visitors representative of scientific and technical institutions, Government departments, and industrial organisations were present and were received by Sir Ernest Rutherford, president of the Royal Society and chairman of the General Board of the Laboratory, Sir Richard Glazebrook, chairman of the Executive Committee, and Sir Joseph Petavel.

The varied nature of the work of the laboratory was well illustrated by a large number of interesting

On the new whirling arm in the Aeronautics Department. measurements were being made of the rolling moments at a steady rate of turning of a model Bristol Fighter aeroplane With the whirling arm stationary a definite moment about the axis of flight can be impressed on the model by magazing. flight can be impressed on the model by means of a spiral spring situated inside it. The resulting displacement effects a separation of the primary and secondary coils of one of two similar electromagnets, the other of which is mounted in the control room Their primaries are connected in series while their secondary voltages are opposed, so that the displacement produces an out-of-balance current which is indicated by a galvanometer. The speed of the whirling arm can then be adjusted until the galvanometer deflexion is zero, when the air moment at that speed is equal to the impressed moment.

In one of the wind tunnels an investigation of the conditions under which wing flutter may occur was in progress. Points on a selected chord of the wing section are connected by light spring-controlled wires to pivoted levers carrying small mirrors and by suitable optical arrangements their vibrations are recorded on sensitised paper. Permanent magnified records are thus obtained and the vibrations of the wind under various conditions can be directly

compared.

The Engineering Department exhibited apparatus for the electrical integration of wind pressure. The apparatus consists of a number of capsule diaphragms arranged in groups, each of the latter being connected to a Pitot tube The expansion of any group is magnified by a lever the free end of which carries a brush sliding over a potentiometer wire. For each group a determination is made of the potential difference between the brush and one end of the wire, and by previous calibration the corresponding wind pressure can be derived. The experimental arrangements are such that if a number of units are attached to a structure, the sum of their potential differences is proportional to the mean wind pressure on the Of interest also was a motor trailer structure. equipped for experimental work in connexion with the wear of road surfaces. An adjustable rear axle permits wheels of varying size from 18 inches to 40 inches diameter to be fitted. Motion of the rear springs is transmitted to recording apparatus in the cab by means of a prvoted lever and bowden wire.
To the coupling is fitted a traction dynamometer, the motion of which is transmitted to the recording apparatus by oil impulses on a plunger in the cab. Determinations are made of the tractive resistance and spring deflexions of the trailer, and of the horizontal and vertical movements of the road surface when the trailer is made to negotiate obstacles of various sizes.

The Metallurgy Department showed apparatus developed for the preparation of beryllium of high purity with the view of eliminating it possible the lack of ductility hitherto associated with this metal Iodine and beryllium produced otherwise are introduced by a side tube into a glass vessel in which is sealed a tungsten wire which can be heated electrically. The apparatus is exhausted and heated in a furnace until beryllium iodide is formed. At this point the tungsten wire is heated up until a temperature is reached at which the vapour pressure of the solid beryllium is less than its partial pressure in the gaseous phase, when solid beryllium is deposited on the wire

A method was also demonstrated of determining the surface tension of molten metals by means of bubbles formed on the ends of two concentric silica tubes, the ends of which are ground in the same horizontal plane, dipping in the metal. The alundum crucible containing the metal and the two tubes are surrounded by an artight furnace through which hydrogen is passed. By means of a special reservoir and valves, bubbles of hydrogen can be blown on either tube, the pressure required being indicated by a manometer. From these pressures and the dimensions of the orifices the surface tension can be calculated.

In the Metrology Department was exhibited an ingenious method of determining the cross-section of very fine quartz fibres which, owing to diffraction effects, do not lend themselves to direct measurement by projection methods. The fibre is mounted horizontally and can be loaded at its mid-point with small milligram riders. A magnified image of the fibre is projected on to a screen, and from the length and displacement of this image under different loads its extension and the forces acting along its axis can be computed. From these data and the known value of Young's modulus for quartz, the cross-section of the fibre can be readily determined

Of interest also was a sensitive tilting level for the Two fixed accurate testing of surface plates horizontal rods, on which the level can slide, bridge the specimen, and the level is racked down until its ball feet rest on a parallel block placed on the surface and moved to successive positions. An image of the bubble thrown on a scale by a semi-silvered glass plate indicates any departure from flatness, which can be computed from the radius of curvature of the level and the size of the block to one hundred thousandth of an inch.

For work in connexion with the international temperature scale a new valve-controlled highfrequency furnace capable of melting up to two kilograms of palladium by the eddy currents generated m the metal has been installed in the Physics Department. The oscillating circuit containing the furnace is included in the anode circuit of two aircooled silica valves connected in parallel and each dissipating 8 kilowatts. The furnace can be exhausted and temperatures are measured by means of an optical pyrometer.

For gas analysis an apparatus utilising high frequency vibrations has been developed. A piezoelectric quartz crystal maintained in vibiation by an oscillatory circuit is used to generate high-frequency sound waves in the gas mixture and stationary waves are formed by means of a movable reflector. When the reflector is identified with a node, resonance occurs between the gas and the crystal, which manifests itself by a large increase in the current in the maintaining circuit after the manner described by Pierce. Measurement of the wave-length then affords a measure of the composition of the gas mixture

A demonstration was given of the determination of flame temperatures by spectrum line reversal. An image of the bead of a Pointolite lamp was focused through a flame on to the slit of a spectroscope. When sodium was introduced into the flame the sodium lines were visible either as bright or dark lines superimposed on a continuous spectrum according as the flame temperature was greater or less than that of the bead. By careful adjustment of the temperature of the latter the sodium lines could be made to disappear. The temperature of the flame was then determined by measuring that of the bead with an optical pyrometer.

In the Optics Division a photo-electric spectrophotometer of general utility was exhibited, and its use for the measurement of ultra-violet absorption was demonstrated. Two monochromators in series are utilised to effect spectroscopic purification of the light from a mercury vapour lamp. The radiation then passes into a photo-electric cell fitted with a quartz window, and the photo-electric current can be measured by either a Lindemann or a Compton

electrometer

In the Electrotechnics Department was to be seen a non-reactive high resistance for use in high voltage alternating current work involving the measurement of very small power factors. Essentially it consists of a number of vertical glass tubes through which tap water can flow, arranged in parallel, and so disposed that two of them which carry the current to be measured are encircled by the remainder. The latter

screen the inner tubes, thereby reducing their capacity to earth and the consequent phase error in the current.

The Electrical Standards Division showed new apparatus for building up standard telephonic frequencies. Between the prongs of a tuning-tork controlled by a seconds pendulum is an iron-core-l bobbin which is included in the anode circuit of a multivibrator of the same frequency as the tork. By means of a selector circuit loosely coupled to the multivibrator, successive harmonics of the impulse

can be picked off.

In the Photometry Division experiments were in progress to determine the effect of a glaring source of light on the ability of the eye to detect brightness differences. An observer seated in a totally enclosed cabinet views a field of uniform brightness except for a circular central spot the brightness of which can be varied until it is no longer visible to the observer. Under glare conditions a circular spot of very high brightness is included in the field. The least difference of brightness detectable with and without glare can then be determined.

The Wireless Division exhibited an installation for investigating the distribution of current in a vertical cage aerial and for determining whether its variation is sinusoidal under transmitting and receiving conditions. Small ammeters are fixed at convenient intervals inside the aerial in order not to affect the capacity of the latter and are viewed from the ground by means of a telescope.

At intervals during the inspection, demonstrations were given in the William Froude Tank to indicate the manner in which measurements are made of the characteristics and behaviour of model sea-going

vessels.

# The Edinburgh Meeting of the Society of Chemical Industry.

A DISTINCT biochemical tendency was noticeable in the contributions brought before the annual meeting of the Society of Chemical Industry, held at Edimburgh on July 4-9 at the invitation of the Edimburgh and East of Scotland Section of the Society. In his interesting presidential address, entitled "Chemistry in the Progress of Medicine," Mr. F. H. Carr stressed the importance of a close co-operation between academic laboratories, research institutions, and industrial establishments in the search for new remedial agents, and of an equally effective liaison between the chemist, the physiologist, and the physician in elucidating the relation between chemical constitution and therapeutic properties. The body hormones are to be regarded as ideal specific drugs, the detailed study of which should do much to illuminate this problem.

Although many such agents are undergoing investigation at the present time, it can be claimed only in two or three instances that the hormone has been solated as a pure chemical individual. Adrenalme, the active principle of the suprarenal gland which plays an important part in regulating the blood pressure, has been synthesised both in the laboratory and the factory. Recently also, a similar advance has been made by Harington and Barger in the artificial preparation of thyroxine of the thyroid gland; 5 mgm to 10 mgm, of this perfectly definite substance may increase the metabolic rate of the human body by so much as 45 per cent, over a period of 14 days. Histamine, another fully characterised substance which has been shown to influence the circulation and respiration, is also apparently produced for functional

purposes in the body.

It is possible that such sub-tances are altered and elaborated in various ways in the body before being able to exert the physiological effects which are attributed to them. In general, although the action of a therapeutic agent is probably determined by its chemical constitution, the body mechanism plays an important part in the resultant chemical changes. It appears that the most effective chemotherapeutic agents act through the formation of a depôt from which they are automatically released as required depôt formation, mechanism of release, and activity in great dilution are indicated as the likely desiderate of chemotherapeutic compounds.

Most of the bacterial and parasitic diseases, as well as others due to defective functioning, await chemotherapeutic investigation. Chemotherapy is but one of the frontiers of scientific medicine, but it may well prove to be the most important. Certainly this will be so if, in the end, we learn how to stimulate at will the chemical processes of bodily defence, and thus to meet every eventuality, or to prepare substances comparable in activity and specificity with diphtheria antitoxin. Progress lies in the direction of biochemistry and more effective working contact between individuals in chemistry, bacteriology, physiology, and clinical medicine. We need to multiply a hundred times discoveries like those relating to the oxidation and reduction phenomena in the tissues, to the constitution of glutathione and of thyroxine. As these results become known, and with the fuller development of experimental technique. we need bold hypotheses like that of Ehrlich so as to open up new avenues of thought and work.

a discussion was held on "The Physiological and Industrial Aspects of the Chemistry of Carbohydrates." Recent work on structural relationships in the carbohydrate group was reviewed in papers contributed by Prot. W. N. Haworth and Prof. A. R. Ling. Di. C. G. Lambie, in dealing with the question of the intermediary metabolism of carbohydrates, advocated the view that dihydroxyacetone may be a possible common term in the metabolic transformations of carbohydrates, fats, and proteins; an assumed equilibrium of the form glucose  $\rightleftharpoons$  dihydroxyacetone, favoured in the forward direction by the presence of insulin, would then explain many of the observed facts of normal and pathological metabolism, including the phenomena of diabetes.

The industrial importance of carbohydrates was emphasised in a paper by Drs C J. J. Fox and L. Hall, in which certain recent developments in the cellulose industries were outlined. Despite the present enormous production of artificial silk, it is considered that the further applications of this material are almost unlimited. The rapidly growing demand for wood in industry renders imperative a considered study of forest economics and the adoption of a policy of afforestation which will maintain an adequate supply of this indispensable raw commodity. Of cellulose derivatives the acetate is practically non-inflammable and has other advantages over the nitrate, but it has not yet attained the level of quality and price which would enable it to displace the nitrate in the manufacture of films, etc. The study of the bacterial decomposition of cellulose by methane producers, hydrogen producers, denitrifiers, and thermophilic species has recently been renewed with the object of bringing such processes under productive control. A further paper, on "Some Aspects of the Manufacture of Fibrous Celluloses," was read by Dr. J. L. A. Macdonald before the Chemical Engineermg Group of the Society.

A wide field of industrial chemistry was surveyed A wide field of industrial themistry was surveyed by the Society's medallist, Col. G. P. Pollitt, in his lecture on "The Development of the Synthetic Nitrogen Industry in Great Britain." The decline in the utilisation of fixed nitrogen which immediately followed the War has been followed by a rapid recovery. In 1926 the world's consumption of ntrogen was 1,250,000 tons, the production having been approximately doubled since 1921. At the present rate of increase of population, and with no alteration in methods of farming, a food shortage is to be anticipated before the end of the present century. As a consequence of the necessity for increasing the output per unit of agricultural land, the nitrogen industry will become one of the most important manufactures, ranking with coal, steel, and ship-building. For economic reasons, synthetic nitrogen is gradually replacing Chile saltpetre and by-product ammonia; but such a replacement was rendered possible only through the development in Germany of the Haber-Bosch process. In Great Britain the technique of high-pressure operations has now been mastered, and there is no necessity for this country to continue indefinitely the importation of fixed nitrogen.

Among other important processes which there is a strong promise of developing in order to render Great Britam less dependent on imported raw materials are the production of liquid fuel by the hydrogenation of coal, of synthetic methanol from water-gas, and of acetylene and acetic acid from coke-oven gas. In the past there has been a tendency for an undue proportion of the most able men in Great Britain to neglect industry and to enter the services, the law, and other non-productive professions. Provided that

in the future our industries have, as in Germany, the first call on the brains of the country, there is every reason to anticipate that Great Britain will continue to lead in the world's industrial development.

Prof J. Read's lecture on "Natural Sources of Energy in Australia" afforded an appropriate indication of the world-wide interests of the Society of Chemical Industry, which has a strong membership in the Dominions and in the United States possesses a surprising variety of power resources, located mainly in the eastern coastal zone. The most important of these are black coal, brown coal, and water power; in addition there are relatively unimportant occurrences of natural petroleum (Papua), natural gas (Queensland), and kerosene shale (New South Wales). For the present the vast deposits of brown coal near Melbourne are to be utilised solely by direct combustion of the raw material the auspices of the State Electricity Commission of Victoria the first section of a power-house, with a present capacity of 50,000 kw., has been erected at Yallourn; it is proposed eventually to raise the capacity to 150,000 kw, and to interconnect the brown-coal power system with the Sugarloat-Rubicon and Kiewa River hydro-electric schemes. The consequent generation of cheap electric power, light, and heat should lead to a steady industrial expansion in this area. Hydro-electric power is being rapidly developed, particularly in Tasmania, more than 500,000 h p. having been located and surveyed in the island. A total amount of 75,000 h.p. is now available from the Great Lake and Shannon River schemes, and factories for the production of electrolytic zinc, carbide, etc., have been established in the vicinity of Hobart.

The Universities of Edmburgh, St. Andrews, and Aberdeen, which he within the area embraced by the local section of the Society, were officially represented at the meeting, and Dr. Kurt Meyer attended on behalf of the German Chemical Society. Prot. A. W. C. Menzies conveyed an invitation from the American Section to hold the annual meeting for 1928 in New York, and this was unanimously accepted.

# University and Educational Intelligence.

Cambridge.—J. A. Ratcliffe, Stokes student of Pembroke College and formerly research student of Sidney Sussex College, has been elected tellow of Sidney Sussex College and University domonstrator in physics. J. A. Steers, St Catharme's College, has been appointed University lecturer in geography, and E. G. Dymond, St. John's College, University demonstrator in physics

After some delay, the deeds executed by the late Mr. W. W. Rouse Ball of Trinity College, by which various sums were to be paid to the University, are being completed, and two sums of £25,000 each will be received for the foundation of professorships in mathematics and modern English law, and a further sum of £10,000, of which the income is to be available for the University Library.

MANCHESTER.—Dr. H B. Maitland has been appointed professor of bacteriology and director of the Department of Bacteriology and Preventive Medicine in succession to Prof. W. W. C. Topley. Prof. Maitland graduated in medicine and surgery in the University of Toronto in 1916 and obtained the degree of M.D. by thesis in 1922. He remained at Toronto as lecturer in bacteriology and later as associate

professor until 1924. Early in 1925 he was appointed to assist in research upon foot and mouth disease, later taking charge of the investigations, and he has since joined the staff of the Lister Institute.

Dr. A. J. Bradley has been elected to an honorary research fellowship in physics.

At the annual Commencement Exercises held at Yale University, Newhaven, U.S.A., on June 22, among those upon whom the honorary degree of Doctor of Science was conferred was Sir James Colquhoun Irvine, Principal and Vice-Chancellor of the University of St. Andrews

ANOTHER series (the sixth) of "Methods and Problems of Medical Education" has been issued by the Rockefeller Foundation. Twenty-eight institutions or special departments of institutions are dealt with in this series; it includes medical libraries and departments of anatomy, physiology, pathology, embryology, neurology, tropical medicine, physicotherapeutics, and others. An interesting article on the value of visual methods in education and methods of projection is contributed by Prof. Jacobj of Tubingen. Details of the staffs, salaries, wages, and cost of upkeep, and methods of instruction are given in most instances, together with plans and illustrations of the institutions and laboratories.

The first report of the English committee dealing with the same portion of the terms of reference as are dealt with in its first report by the Committee on Education and Industry in Scotland, namely, ". . . . particular reference to the adequacy of the arrangements for enabling young persons to enter into and retain suitable employment," was published at the end of last year (see NATURE, Jan. 8, p. 69). Necessarily, and obviously, the two committees have been closely in touch with each other. Among the recommendations common to both are: closer cooperation between juvenile employment committees and juvenile advisory committees; the appointment of qualified officers and the provision of suitable premises for choice of employment; a national advisory council for juvenile employment; the increase of information as to industrial conditions available to juveniles and parents; provision of public money for the purpose of a scheme of juvenile unemployment centres; legislation to cover the provision of working certificates. Both committees have seen quite clearly that between the ages of fourteen and sixteen years, "boys and girls are most impressionable, and irretrievable damage can be effected by enforced idleness." Yet during this very period there is a gap in public supervision, since the age of entry into unemployment insurance is sixteen years. Two remedies present themselves immediately: the raising of the school leaving age, and the lowering of the age of entry into unemployment insurance. With regard to the first, the English committee appeared overwhelmed by the evidence against raising the school leaving age, and became correspondingly vague: "the change, if made [our stalics], should be made for educational and social rather than industrial reasons' The Scottish committee is much more vigorous. "Due notice should be given by the Scottish Education Department, as soon as it may be found financially practicable, of the appointed day for the raising of the school leaving age to 15 years. . . . When, but not before, the school leaving age is raised to 15 years, the age of entry into unemployment insurance should be lowered to 15 years."

# Calendar of Discovery and Invention.

July 17, 1850.—The earliest photographs of stars were those of Castor and Vega obtained on July 17, 1850, with the refractor at Cambridge, Mass, by Whipple under the direction of W. C. Bond.

July 18, 1774.—The first experiments in Great Britain for determining the mean density of the earth were made by Maskelyne in Perthshire, who on July 18, 1774, wrote to Dr. Lind: "From the observatory on the south side of Schiehallien . . . I am now ready to begin making observations . . . whenever the weather will permit." The results of Maskelyne's observations worked out by Hutton gave the value 4.481. The

experiment cost the Royal Society £597:16s.

July 19, 1846—One of the many students of Liebig at Giessen was Frank Buckland, who, writing on July 19, 1846, gave his routine thus. "7.30-8 30, chemistry; 9-10, German with Dr. Adrian, 10-11, laboratory; 11-1, Liebig's lecture; 1-2.30, dinner. After dinner I occupy myself with chemistry in the laboratory, or German, as the case may be, till about 6 or 7. If ever there was a place to work in it is Giessen. The people never think of leaving off work till 6 or 7; whereas at Oxford the books are shut up at the latest at 2 o'clock"

July 20, 1854.—Liebig retired from Giessen in 1854. The English chemists, headed by Graham, sent him a testimonial "Commemorative of their profound and unalterable regard." Acknowledging the gift from Munich on July 20, 1854, Liebig began his letter: "The man of science generally knows of no other reward for the time he has devoted to the discovery of truth and to the investigation of the laws of Nature's powers, than the mental satisfaction which springs from the consciousness of having, to the best of his ability, contributed his part towards the advancement of human happiness and human welfare; for toils like this, attended as they are with so many difficulties and sacrifices, and with such mental effort and fatigue, cannot be priced in the market or sold -cannot be performed to order or turned into money. . . If I have laboured for the period of almost a human life in promoting the progress of chemistry . . . I gratefully acknowledge that I have received in return all that a man could justly aim at."

July 21, 1820.—It was between July 15 and July 20, 1820, that Oersted made his remarkable discovery of electro-magnetism, the results being made known to the world in a circular letter in Latin, dated July 21, 1820: "Experimenta circa effectionem conflictus electrici in acum magneticam." Oersted's discovery was the result of a long search for a connexion between electricity and magnetism.

July 21, 1914.—Working at Lick Observatory, Nicholson, on July 21, 1914, discovered photographically the ninth satellite of Jupiter, which, like the eighth satellite, revolves around the planet in an opposite direction to the other seven.

July 23, 1849.—On this day Fizeau communicated to the Paris Academy of Sciences the results of his determination of the velocity of light by measuring the time taken for light to travel between Suresnes and Montmartre, a distance of 28,334 feet.

July 23, 1847.—Among the important contributions to the early work on the new theories of the conservation of energy and the mechanical equivalent of heat was the memoir of Helmholtz, "Über die Erhaltung der Kraft," read to the Physical Society of Berlin on July 23, 1847. The paper was, however, refused admission to Poggendorf's Annalen, and among the older members of the Physical Society, Karl Jacobi was the only supporter of the views of Helmholtz.

# Societies and Academies.

LONDON.

Royal Society, June 30 —C. Chree and J. M. Stagg: Recurrence phenomena in terrestrial magnetism. Making use of the daily international character figures for 1906 to 1925 issued from De Bilt, an attempt is made to enlarge our knowledge of the 27-day interval in terrestrial magnetism Assuming magnetic disturbance to be caused by some kind of electrical discharge from the sun, if sunspots were the sole or principal source of the discharge, we should expect the interval to be longer in years of high than in years of low spot latitude. No recognisable difference is, however, found. In opposition to results obtained by Dr. Deslandres, no trace is found of periods which are submultiples of 27 days On the other hand, days which follow from 4 to 6 days after a very quiet day prove to have a greater than average chance of being highly disturbed days.

S. Chapman: On certain average characteristics of world-wide magnetic disturbance The average characteristics of slight magnetic disturbance in the middle belt of the earth, between northern and southern latitudes of 50° or 60°, are similar to those of intense disturbance (magnetic storms) in the same

region.

Taylor: The distortion of crystals of aluminium under compression (Part ii.). Changes in orientation of crystal axes during compression of a disc cut from a single crystal of aluminium are in accordance with the prediction made on the assumption that the crystal slips as determined by distortion measurements. As with tensile test pieces, the crystal axes always take a position where two possible planes of slip are symmetrically disposed in relation to the stress, but the orientation is different. After the axes have taken the symmetrical position, they remain there, even when distortion is very great. Distortion during the period when the crystal axes remain in the symmetrical position is due to slipping on two symmetrically disposed planes of slip

G. I. Taylor: The distortion of crystals of aluminium under compression (Part in.). Several experiments were devised to find out whether it is possible to measure the internal stresses in a compressed disc. The relationship between shear stress and amount of shear is found for tensile and for compression specimens, when slipping is confined to one plane. The experimental results in the two cases are identical. The fact that the component of force normal to plane of slip is a pressure in one case and a tension in the other makes no measurable difference to resistance to slipping for given amount of slip. During double slipping, resistance to shear increases more rapidly for a given total amount of slipping than when all slip is confined to one plane. Resistance to shear goes on mcreasing up to the greatest amounts of distortion used.

Prof. J. C. McLennan, H. J. C. Ireton, and K. Thomson: The luminescence of solid nitrogen under cathode ray bombardment. The phosphorescence bands  $N_2$  (5230 Å.U.) and  $N_4$  (5945 Å.U.) have complex structures, the former having eight and the latter three components. The moment of mertia of the molecular system involved in the phosphorescence of solid nitrogen is  $3\times 10^{-40}$ . The group of bands  $N_1$  near 5577 Å.U. originate in a modification of nitrogen different from that involved in the production of the

bands N<sub>2</sub> and N<sub>4</sub>.

E. T. Paris: On the reflexion of sound from a porous surface. The 'acoustical admittance per unit area ' can be measured experimentally by means of

Continued from p. 66.

the 'stationary-wave' apparatus for testing soundabsorption, and when it is known, the coefficient of absorption (for the particular wave-length at which the admittance has been measured) can be calculated by a simple formula for any angle of meidence. For an 'acoustic plaster' there is a large variation of absorption with change of angle of meidence, the coefficient increasing from 0.28 at normal incidence to 0.76 at about 83° and then falling to zero at grazing incidence. Heavy absorption at very oblique meidence appears to be characteristic of plasters of this kind.

C. J. Smith. A new differential dilatometer for the determination of volume changes during solidification. The dilatometer has two bulbs immersed in a thermostat, the change of volume of the substance contained in one bulb being compared with that of a corresponding volume of nitrogen in the other. The difference of pressure of the nitrogen in the two bulbs is measured by withdrawing a known volume of mercury from a small reservoir attached to the appropriate side of the dilatometer. The advantage over other dilatometers used for the same purpose lies in the possibility of obtaining definite and steady

conditions of temperature.

R. C. Johnson and H. G. Jenkins. The band spectra of silicon fluoride. Some eight band systems or groups—all except one new—are recorded and attributed to silicon fluoride. Two band systems attributed to a fluoride of sulphur were encountered in the experimental work. To two of the band systems of silicon fluoride, named  $\alpha$  and  $\beta$ , have been assigned vibrational quantum numbers. A third, the  $\gamma$  system, is shown to be related, and a fourth system has been partially analysed. The heat of dissociation of the FS1-S1F molecule is of the order of 5 volts or 116000 calories.

T. W. Wormell: Currents carried by point-discharges beneath thunderclouds and showers. Upward currents were found generally greater than downward The maximum value attained during a shower by the discharge current from the single point, which was at a height of about 8 metres, was frequently between 1 and 10 microamp. The net quently between 1 and 10 microamp. The net quantity of positive electricity discharged during a shower was commonly of the order 10-2 coulomb. The total net transfer of positive electricity from the point during 8 months was  $0.17_3$  coulomb, the quantities passing upward and downward being  $0.25_5$  coulomb and  $0.08_2$  coulomb respectively. The transfer of electricity observed is thus opposite in direction to the normal ionisation current of fine weather, and also to the convection current carried by precipitation. In the case of several showers, the phenomena observed consisted of a downward current as the cloud approached, a large upward current beneath the centre of the shower, and a downward current towards the end of the shower. The distribution of electric field below the cloud suggests that in these cases the cumulo-nimbus cloud was bipolar,

with upper charge positive, and lower charge negative.

A. M. Taylor and E. K. Rideal: The effective moment of the sulphur complex. The absorption spectrum of sulphur has been examined in the infrared between  $1\mu$  and  $14\mu$ . The chief maxima occur at  $7.7\mu$  and  $11.9\mu$ , and the form of curve is the same for rhombic, prismatic, liquid and plastic varieties, the maxima being very little shifted from one modification to another. The depth of the absorption band at 11  $9\mu$  is somewhat remarkable, in view of the absence of charged ions in the element. The 'effective charge' on the vibrating particles in sulphur is about 0.7 electron, indicating an interatomic linkage which approximates to one of heteropolar character. Assuming the group  $S_2$  to have an electric moment, a structure is suggested for the larger group  $S_{16}$ , and the electric moment of the group  $S_2$  is calculated. The value agrees with that determined from the infra-red spectrum.

Academy of Sciences, June 7—Ch. Depéret. An attempt at the Phocene history of the Seine basin—Edouard Imbeaux: The great Artesian basins of Russia in Europe.—Léon W. Cohen: The non-equivalence of the definitions of dimensions of Menger and Urysohn—Gr. Fichtenholz: Suites of harmonic functions.—Henri Chrétien: Panoramic kinematography by means of ordinary apparatus.—R. de Mallemann. The general molecular theory of rotatory power—P. Bonet-Maury: The vaporisation of polonium. The polonium preparation is carried on a ribbon of nickel, the latter being heated electrically to a known temperature. Just above this is placed a copper vessel containing liquid air and the volatilised polonium is completely deposited on this cooled surface. This apparatus has been used to determine the law according to which the volatilised atoms of polonium are distributed in space when the heating is carried out in a vacuum—F Blondel The structure of the ensemble of the south-east of French Indo-China.

#### BRUSSELS.

Royal Academy of Belgium, Jan. 8 — Octave Dony and Francis Meunier: The electrolysis of the insoluble compounds of the alkaline earths and, in particular, of barium carbonate. A comparative study of the conditions of electrolysis of barium carbonate in suspension in a solution of chlorate or perchlorate of the same metal, in the case where the two electrodes are separated by a diaphragm (Siemens and Halske method), and in the case where the use of a diaphragm is replaced by that of a mercury cathode. The conditions of yield are found to be more favourable in the latter method.—Th. De Donder: The extremals described by electrons and electrified particles.—F. Dacos: The specific inductive power of phosphorescent substances. Experiments are described showing that for a series of preparations of calcium sulphide containing an increasing proportion of impurity (bismuth) the specific inductive capacity of the various substances as well as the intensity of the light emitted by the phosphorescence follow an analogous law. It has also been shown that the dielectric constant of a phosphorescent substance remains invariable whatever the illumination to which it may be submitted.—E. Dahy: A birational involutive transformation of the plane—M. Bazzin and A. Errera: The logic of M. Brouwer.—R. Moens: Some experiments on the electrodeless discharge with maintained waves.

Feb. 5.—Th. De Donder: Extremals described by electrons and electrified particles. (Second communication.)—P. Swings: The quasi-elliptic orbits, Riemann potentials, and central forces.

#### GENEVA.

Society of Physics and Natural History, May 5.—L. Reverdin. Study of the fauna of the station of Sumpf (Zoug), bronze age—The author has identified 298 bony remains belonging to 11 species in addition to man, amongst which he gives a description of ox, sheep, and dog, the last represented by two kinds, the dog of the bronze period and that of the peat period. The fauna corresponds with that of Alpenquai, at Zurich—R. Chodat: Two new algae in the flora of the Lake of Geneva. The author has observed in the water of the lake in large quantities a new species

of Pandorma and a new Erueigenia, not before noted in spite of twenty-five years of careful research. It is a rare case of epidemic stocking in a lake basin in floral equilibrium.—H. Lagotala Contribution to the study of the ancient strands of the Mediterranean. A strand 8 or 9 metres high is visible at Cavalaire (Var., France). It is marked by holes due to molluscs and corresponds well to the lines of strands pointed out by Depéret, Caziot, and others

#### WASHINGTON

National Academy of Sciences (Proc., Vol. 13, No. 4, April) —J L. Walsh. On the expansion of harmonic functions in terms of harmonic polynomials.—B. P. Gerasimovič: On the correction to Saha's formula for small deviations from thermodynamic equilibrium. The applications of ionisation theories in astrophysics assume that the layers in which spectral lines arise are in thermodynamic equilibrium. This can give only approximate results. The correction for small deviations from equilibrium is calculated. For the sun, it is nearly unity because the 'boundary' temperature (Schwarzschild) does not differ from the temperature measured spectrophotometrically, for some of the stars showing emission lines it may be of importance.—Worth H. Rodebush: Chemical constants and absolute entropy. Using the specific heats at low temperatures, the vapour pressures at low temperatures, and the specific heats of the liquid metals, the entropies of potassium and sodium vapours at 298° K and 1 atmosphere are found to be 38 2 and 36 7 respectively. These values suggest that the thermodynamic probability of a system is a definite number and justifies the concept of absolute entropy.—Richard C. Tolman, Don M. Yost, and Roscoe G. Dickinson On chemical activation by collisions. In discussing activation by molecular collisions, the amount of energy available is generally only slightly in excess of that required for activation. This entails the unlikely effect that practically all the energy after a collision passes into one of the colliding structures. Further, the hypothesis leads to very large values for the de-activational diameters, and also to the use of different diameters for activational and de-activational collisions.—Alfred C. Robertson: A case of negative catalysis in a homogeneous system. Vanadic acid (ammonium vanadate +acetic acid) greatly diminishes the rate of decomposition of hydrogen peroxide by potassium dichromate. It is suggested that the intermediate perchromic acid is converted into the less reactive pervanadic acid, thereby decreasing the total rate of decomposition.—T. H. Gronwall: On the determination of the apparent diameters of the ions in the Debye-Huckel theory of strong electrolytes. -Joseph W. Ellis: New infra-red absorption bands of methane. Five new bands at and between  $\lambda 1.15 \,\mu$ and  $\lambda 1.80 \mu$  were observed. Certain bands at and between  $\lambda 1\cdot 15~\mu$  and  $\lambda 7\cdot 67~\mu$  seem to be associated with the C-H linkage.—Ernest O. Lawrence and J. W. Beams · On the nature of light. By passing light from a zinc spark gap through a Nicol prism, a double Kerr cell consisting of two sets of parallel brass plates in carbon disulphide and oriented at right angles to each other and at 45° with respect to the electric vector of the polarised light, and finally through another Nicol prism 'crossed' with respect to the first, it was possible to obtain short 'segments' of light of variable length. The effect of these pulses was measured by a potassium photo-cell. Such segments might include fractions of light quanta, which would be unable to eject an electron photo-electrically; also, the time taken by the 'segment' to pass over an electron might be less than the time required to eject an electron. Thus, the photo-electric current would be small or zero. The results

show that light quanta, as generally understood, are less than 3 cm long, and that an electron absorbs a light quantum in less than  $10^{-10}$  sec —L. A. Sommer: Bands in the extreme ultra-violet spectrum of a helium discharge. Lyman's so-called line at λ600 3±0.6 appears to be a band corresponding to a transition  $1^1S-2^1S$  in the helium molecule.—W. N. Birchby. White-light interference fringes with a thick glass plate m one path (Part 2).—G W. Stewart and Roger M. Morrow Molecular space array in liquid primary normal alcohols · the cybotactic state X-ray circular diffraction haloes in these alcohols show that one distance observed increases by approximately 1.54 Å.U. with each CH2 group added to the chain, while another distance, varying from 4.6 Å U. for lauryl to 3 8 Å U. for methyl, seems to be due to the separation of the molecules perpendicular to the The results indicate a space array permitting of molecular mobility in the liquid which is termed 'cybotaxis.'—Carl Barus. Pinhole probe measure-ments with massive cylindrical air columns.—Jared Kirtland Morse: Atomic lattices and atomic dimen-Models of cubic and hexagonal lattices can be built up using a modified cubic atom concept, and possible atomic radii are calculated. One striking result is that the atomic radius of the carbon atom in diamond is  $0.77\,\text{Å}$  U. while in graphite it is  $0.75\,\text{Å}$ .U., and both lattices consists of cubes having one corner in common.—Paul S. Epstein. The magnetic dupole in undulatory mechanics.—R. A. Brink and C. R. Burnham: Nucleus and cytoplasm in relation to differential pollen-tube growth. 'Sugary' maize plants bear a lower proportion of 'waxy' seeds than plants carrying the dominant 'non-sugary' factor. Recognising two stages of growth in the pollen-tube, dependent respectively on (1) the food reserves of the pollen grain, and (2) on food materials supplied by the tissues of the pistil, a differential rate of growth is found in the first stage —J. T. Buchholz and A. F. Blakeslee: Abnormalities in pollen-tube growth in Datura due to the gene 'tricarpel.' Many of the pollen-tubes from pollen carrying the 'tri-carpel' gene burst at their tips and the protoplasm is extruded, leading to a deficiency in 'tricarpel' individuals in crosses.—M. Demerec: Magenta-alpha -a third frequently mutating character in Drosophila virilis.—Dontcho Kostoff: Pollen-tube growth in Lythrum salıcarıa. Pollen-tube growth in fertile pollinations is accelerated in the later stages in contrast with that occurring in unfertile pollinations.-William Hovgaard: Bending of a quasi-ellipsoidal shell with special reference to rigid airships. Two deformations other than simple bending are involved: (a) a downward movement of the framework due to shearing deflexions of the whole ship; (b) a deformation of the transverse frames due to unequal loading. -H. Walter Leavitt and John W. Gowen: Influence of iron content on mortar strength. The tensile strength of mortar (after both 7-day and 28-day periods) increases with increasing iron content in the sand used; compressional strength is unaffected.

#### Education and Science.

THE beginnings of education have not hitherto seemed very relevant to the interests of scientific men. They have been anxious to make good the place of science in all the important later stages of education, not merely for professional training, but also as an essential part of any wide, civilised perspective appropriate to our time. They have offered their own contribution of method, in the heuristic form, as a valuable and typical educative experience. But whilst their professional demands have been more or less satisfied, the cultural assimilation of science makes slow progress. It is still treated as an alternative to the humanities. It still appears to many educated people as a form of specialism irrelevant to general education.

Perhaps it is the belated and limited introduction of science which perpetuates this disjunctive view and prevents the true value of science for liberal education from being seen. If it is thus made to appear as a new and separate beginning in knowledge, leading away into a special field, it can scarcely do otherwise than disconnect this field, and the limited number who enter it, from the general body of future educated opinion which stays outside and indifferent.

If, however, the world of science is only the common world greatly enlarged and much more adequately known, and if its methods are the methods by which such more adequate knowledge is achieved, then guidance to some understanding of this would clearly need to be recognised as a major aim for any humane education. If that aim were defeated by any late and separate beginning in science, that would be a serious limitation, not of the educative value of science, left unused, but of the prevailing order and method of education which kept it so. It would then be necessary to trace the disjunction between science and the common world back to its source in the current educational process and to seek to remedy it there. The earliest stages would thus become very important and the question would arise whether they could not be so ordered from the beginning that this false disjunction could never arise at all.

Specialisation would come at its due late time, as now, for those whose interest led them to it, but it would be continuous with a liberal general education which aimed at making some representative sense of the scope, aims, and methods of scientific knowledge a common possession for all.

It is this representativeness that would be aimed

at, graded from the first beginnings of concrete knowledge in the common world to its typical highly developed and organised forms. The value of science for education would then lie in the continuity of its character and history being made available for a parallel continuity of development in knowledge of the child. The approved method of starting science learning at some rudimentary concrete beginning, at whatever age it is begun, which can easily be made to seem highly artificial, would receive its natural meaning if it set out from the age where the simplest kind of direct knowledge-learning actually began.

We should thus be proposing not another fixed programme or schedule, but a difficult and important problem in liberal education. It would become a matter for careful and scientific study what was the best manner and sequence of procedure, in order to preserve the continuity of method and perspective at which we should aim. We should have a valuable initial advantage over formal subject-knowledge and subject-teaching because we should be working with a powerful native educative interest in the child, but it would be a part of our problem, and a very central one, to preserve this interest and to carry it on.

The first direct knowledge-learning from which we should start would thus be that which emanates from the child itself, spontaneously and usually actively. Most normal children of, let us say, 4-5 years of age show a lively, inquiring curiosity in the world around them, and want to know how things work, what they are, how they are made. Their curiosity seeks knowledge and takes pleasure in finding it. We should be endeavouring so to guide, reinforce, and develop this curiosity of the normal child in the world around him that it could pass continuously by its own activity into the same interest, informed and organised, in the world—not different but greater—of science.

We should, of course, not assume that this could be done, but should be content with not laying down in advance that it could not be done. A critical examination of all the avoidable ways of preventing, restricting, discouraging, misdirecting, or confusing the advance of knowledge, familiar to us in the history of knowledge of the race, but not all and always avoided in that of the individual, would show the evidence against us to be at least inconclusive. It would be possible that the interlocking quality of the older system of formal knowledge, formal teaching, and enforced receptivity gave rise to what evidence there was; and whilst this system would have to continue in some partly mitigated form so

long as we knew no other way, it would be important to try any way in which we might conceivably learn better. To endeavour to establish a high road from natural curiosity to representative scientific knowledge would at any rate be to test one possible way.

In the meantime we should have this initial interest in the child to work upon, to stimulate and encourage, to refer to active, direct inquiry, to provide with graduated experience of the relation between such inquiry and discovery, and to carry on to a more and more developed sense of the terms on which knowledge could be gained, tested, and enlarged in an enlarging world

This would then make a formidable problem for highly skilled research. It would, of course, only be a part of the problem of progressive education, since for the point of view here adopted, scientific knowledge is far from being the only kind of knowledge, or knowledge the only aim of education. Thus, for example, taking knowledge alone, a historical perspective upon science itself, and this in turn set in some just proportion in a larger historical whole, would clearly be a like condition and eventual aim for the process of scientific educa-But there would be reason for sugtion itself. gesting that the scientific way would be the first, easiest, and most natural way of beginning education and establishing some foundation of direct experienced knowledge and its way of increase, for later indirect knowledge to be built upon.

That would be in full accord of principle with the recent trend of enlightened educational theory, which, coming more and more under the influence of psychological knowledge, itself advancing, aims at grading the processes of education from the start so that they should flow easily and naturally out of the child's development. In practical progress it has inevitably remained conditioned by the powerful tradition which it has sought to change but within which it has had to work; and its scope has thus been rather to liberalise old methods and subjects and gradually to bring them closer to the child, than to consider any more radical possibilities of theory. For the further advance of education, however, it is necessary that these more radical possibilities should be fully worked out, and, according to their promise, practically tested.

Given now the aim of adaptive grading and psychological integration, and given also the inherent limits of a vast deal of traditional knowledge which can only be communicated verbally and by methods more or less unrelated and arbitrary, it is a crucial problem for psycho-

logical education whether there is no other knowledge, which can be developed first, from natural roots; and carried on continuously by the same methods to a high integration, as a pattern and framework of what knowledge can be. The natural continuity of science provides a possible solution alike for a first beginning of education in knowledge and for its organic development later

To make this solution actual, however, there is needed practical research of a high order, fundamental in character, by many investigators, bringing wide resources and high qualifications to bear. But if education is important, research in it is important, and its pre-conditions must be fulfilled. We must assume that education may technically only be at its beginnings in order to look for definite ways of verifying this and to press for adequate and multiple research.

Some interesting commencements have been made in recent years, though still somewhat entangled in general programmes of practical education. Thus the Maison des Petits attached to the Institut Rousseau at Geneva, and the Walden School in New York, may be instanced. Perhaps more directly relevant is the Malting House School at Cambridge which specially aims at exploring the educative use of introductory science from the outset of education. During three years, the response of children of 4-7 years of age under free conditions to opportunity and stimulus for the direct discovery of many kinds of natural knowledge-mechanical. physical, biological—has been observed and studied. As, however, this remains an unseparated element in the general plan of humane education of the school, and the number of children is small, any encouraging results obtained can so far only be suggestive. A recent prominent advertisement of this school has set very high standards for a more specific investigation in the same field, and the result should prove significant, but since scientific work is nothing if not cumulative, it must eventually be judged less by what it does than by what it begins. What is important, therefore, is continuance, and a sustained movement of similar work. The simple, obvious principle on which the research attitude is based, that facts are only as unalterable as all the conditions on which they depend, and beliefs only as valid as all the assumptions on which they rest, is as applicable to education as to engineering. It should become as much a commonplace in the former as in the latter field that no a priori assumptions, but only the quality, extent, and coordination of actual research done, can determine how much progress is—or is not—possible.

# A Complete Catalogue of Scientific Periodicals.

A World List of Scientific Periodicals published in the Years 1900-1921. Vol. 2 · Abbreviated Titles and Locations of Sets. Pp. xii+344. (London: Oxford University Press, 1927.) 45s. net.

THIS second volume of the "World List of Scientific Periodicals" contains the abbreviations proposed for the titles of the 24,028 periodicals the full titles of which were given in the first volume, a notice of which appeared in Nature of Sept 19, 1925, p. 419. There is a supplement containing 658 further titles as to which information has been received since the publication of Vol. 1. There is also a list of abbreviations proposed for the titles of the reports of some 140 international congresses.

The titles in the previous volume were numbered. In this volume the same numbers appear, followed by the proposed abbreviations. We think, however, that the reader will find, in most cases, that the abbreviations are full enough to make it unnecessary to refer to Vol. 1. Thus the meaning of such an abbreviation as "Bull. Soc. Sci. Nat. Phys., Montpellier," would appear fairly obvious, though, if the reader should wish to quote the exact wording of the title, he would do well to make certain by looking at Vol. 1, for it is explained that such an abbreviation as 'Sci.' may mean science, sciences, or scientific, while 'Bl.' may stand for Blatt or Blatter.

For the convenience of those who may wish to make a card catalogue, the volume is printed on one side only of the paper, so that it can be cut up and pasted on cards

The outstanding feature of this volume, and that for which British science will be most grateful, is the information showing the libraries in which a periodical can be consulted. Those who possess this volume need not fear to be told by a librarian that the journal they wish to consult is not in his library, for they will know beforehand which library to visit. The libraries which have furnished lists of the periodicals on their shelves are in the cities of Aberdeen, Aberystwyth, Birmingham, Bristol, Cambridge, Cardiff, Dublin, Dundee, Edinburgh, Glasgow, Leeds, Liverpool, London, Manchester, Nottingham, Newcastle. Rothamsted, St. Andrews, Sheffield, and Swansea. In London 27 libraries have given full information as to the scientific periodicals they possess, in Cambridge 27 libraries, in Edinburgh 21, in Oxford

19, in Glasgow 9, in Manchester 7, and in Birmingham and Sheffield 6 each. Altogether there are 112 libraries in the list, and against every periodical in the "World List" there is a note showing in which, if any, of these libraries it is available.

It may happen that in some library the series of a particular periodical is incomplete. In the "World List" an attempt is made to give full information as to gaps in the sets. Knowledge that volumes are missing from a series in a library is not only valuable to those who use that library, but also will remind the custodians of the institution that these missing volumes should be supplied as soon as possible.

While it is satisfactory to note the large number of periodicals that are to be found in one or other of the British libraries, there remain very many which, according to this list, cannot be consulted in Great Britain. It would be worth while to make a close study of the entries to see whether some of these missing journals might not take the place of others of which there may be an unnecessary number of copies.

The origin of the "World List of Scientific Periodicals" was explained in the notice of the first volume. At the suggestion of Sir Sidney F. Harmer, until recently Director of the Natural History Departments of the British Museum, and Dr. P. Chalmers Mitchell, secretary to the Zoological Society, the Conjoint Board of Scientific Societies appointed as a Committee Sir Sidney Harmer, Mr. F. W. Clifford, Sir Richard Gregory, Dr. P. Chalmers Mitchell, Dr. A W. Pollard, and Prof. W. W. Watts to consider the possibility of preparing a list of the chief scientific periodicals, with an indication of the libraries in which they might be consulted. This Committee decided to index scientific periodicals in existence from Jan. 1, 1900. Details as to the sets of these periodicals before 1900 may also be given. It was soon found that the cost of preparation and publication of a work of this magnitude could not be covered by subscriptions and sales. Help was given by Sir Robert Hadfield, Mr. Robert Mond, and the trustees of the Carnegie United Kingdom Trust.

In 1923 the Conjoint Board came to an end, but it had previously entrusted the "World List" to Sir Arthur Schuster, Mr. Robert Mond, and Dr. P. Chalmers Mitchell, who formed a company limited by guarantee to complete, own, and conduct the "World List of Scientific Periodicals." This company was incorporated with a council of management consisting of Dr. P. Chalmers Mitchell (chairman), Sir A. Schuster, and Mr. R. Mond.

Miss Joan B. Procter became secretary. The work of the council is voluntary, and by the articles of association no benefit can be distributed to the members of the company. The company holds the copyright of the "World List" and, at a future date, if funds should permit, it will arrange for the issue of reprints and supplements It is also provided in the memorandum of association that if some stronger body were willing to take over the duties and responsibilities of the company, then any surplus funds which may have accrued should be handed over to some "other institution or institutions the objects whereof shall be certified by the President of the Royal Society of London for the time being to tend to the advancement of science" It is therefore quite clear that any one wishing to advance the interests of scientific research by helping to make its published results accessible, may contribute to the funds of this company, confident that his money will not be used otherwise than in the interests of science.

Much skill and an enormous amount of labour have been required in collecting and arranging the titles of 25,000 periodicals, preparing abbreviations, and indicating where the periodicals may be found.

The trustees of the British Museum, on the recommendation of Dr. Pollard, then Keeper of Printed Books at the Museum, supported by Sir Frederic Kenyon, Director and Principal Librarian at the Museum, allowed the compilation of the list to be undertaken by the staff of the Museum as part of their official duties.

The co-operation of the librarians of a large number of libraries in the United Kingdom has made it possible to state the libraries, if any, in which each periodical is to be found.

The original editor of the "World List" was Dr. A. W. Pollard, who was assisted by Mr. W. A. Smith. Mr. Smith, with advice from Dr. Pollard and Dr. P. Chalmers Mitchell, has undertaken the chief burden of editing this second volume Among difficult problems with which the editors have had to deal were those arising from changes in the titles of periodicals. In the reports from the various libraries there was found a want of agreement as to the date on which a change of title had taken place. Much labour was required before these dates could be fixed. The problem was not confined to changes of title during the period 1900-1921 covered by the "World List," for libraries possessing sets of periodicals which started before 1900 and continued beyond that date, were allowed to give details of earlier years. It has therefore been necessary to decide as to the identity of a periodical

under the different names it has borne during its existence

The date at which a periodical ceased to exist has been denoted by an asterisk. The editors found that very few library catalogues give accurate information on this point. They have taken great pains to discover the exact date of the 'death' of all periodicals which have ceased publication to be found in libraries in Great Britain, but they are not able to guarantee that the information on this point regarding periodicals of which no set is preserved in the country is always correct.

Much importance attaches to the choice of the abbreviations, for these are intended to be used by authors in referring to articles in the journals. The rule that the order of the words on the titlepage of a journal should be followed in the abbreviation has been adopted. Thus the Journal of the Chemical Society of London is abbreviated "J. Chem. Soc. Lond" and not "Chem. Soc J." It is true that this method separates the different publications (Proceedings, Reports, Transactions) of the same Society, but it makes it much easier for the reader to reconstruct the full title. It is greatly to be hoped, for the sake of uniformity, that the abbreviations used in the "World List" will be accepted as the standard of general practice.

The place of imprint is omitted except when needed to distinguish periodicals with the same title; but when the abbreviated form would leave the language of the original uncertain, the imprint is added for all except the best-known language of those between which confusion could arise, the order of familiarity being fixed as English, French, German, Italian, or Spanish. This strikes one as a rather curious rule. We think it would have been better to give the town of publication in all cases except those in which that town is mentioned in the title.

One cannot help asking whether it is really necessary that there should be so many periodicals dealing with science. Perhaps the publication of this list may suggest that some of these journals might amalgamate and so lessen the number which the scientific worker may be called upon to consult.

The two volumes of the "World List" will be of very great value not only to librarians but also to all who have an interest in science. Those who have taken part in their preparation and the Oxford University Press are to be heartily congratulated. All scientific workers will thank Dr. P. Chalmers Mitchell for the resolute way in which he has guided the enterprise through its difficulties and finally brought it to a successful conclusion.

### Physiological Genetics.

Physiologische Theorie der Vererbung By Prof. Dr. Richard Goldschmidt Pp vi + 247. (Berlin: Julius Springer, 1927) 15 gold marks.

PROF. GOLDSCHMIDT has given biologists a very stimulating book. It may be incorrect or incomplete in a number of individual points, but the author will not, we suspect, mind this so long as the book is widely read, and read in the spirit in which it is clearly intended, namely, as a pioneering venture into the new and almost uncharted sea lying between genetics and Entwicklungsmechanik, which, with our author, we may call physiological genetics.

It is now fifteen years ago that Goldschmidt published his first paper on the problem, which will be as classical to students of physiological genetics as is Mendel's work on the pea to students of simple (or distributional) genetics—the problem of intersexuality in Lymantria. There, as is well known, he was able to show, first, that intersexuality was produced by a lack of balance between definite genetic factors for maleness and for femaleness; secondly, that this imbalance revealed itself in the time-sequences of development—the intersexes were animals which began their development of the 'right' sex, but later became switched over to the development proper to the other sex, and thirdly, that the greater the upset of balance, the earlier did the 'wrong' sex come to have the upper hand. From these facts Goldschmidt drew the conclusion, which appears as unassailable in its broad outline as is Mendel's conclusion of purelysegregating unit-factors, that the male- and female-determining factors exist in a number of related forms (presumably multiple allelomorphs) differing, inter alia, in their quantitative potency; and that the more potent differ from the less potent in effecting the same reaction more rapidly

In the present volume Goldschmidt seeks to universalise this view, and advances the theory that all Mendelian genes are concerned fundamentally with the rates of developmental processes, and that the differences between allelomorphs can always be reduced to, and indeed best thought of as, differences in such rates of action.

Let us say emphatically at the outset that this is an extremely fruitful view-point. Most geneticists, so long as their experiments led to the discovery of definable gene-units, have been perfectly content to note the mere fact of relationship between gene and character-effect, without attempting to think out how that relationship was brought about.

'The gene for bar-eye,' 'the factor for wrinkled seeds," the gene which produces reduplicated legs in Drosophila kept at low temperature,' 'lethal factors,'-for the most part geneticists have been content with such purely descriptive statements. There have been honourable exceptions. Sewall Wright, following Onslow, has given a most illuminating analysis of all the coat-colour genes of mammals, which is based upon the idea of the interaction of two or three quantitatively-controlled pigmentary reactions; Miss Wheldale has attempted to analyse the relationship between the brochemistry and the genetics of anthocyan pigmentation in plants: the recent beautiful work of Plunkett (J. Exp. Zool., 1926) on the mode of action of bristle-inhibition in Drosophila is one of the greatest value: and there are other examples. But they are all exceptions.

Goldschmidt attempts to generalise. Let us give a few examples. He himself has worked out the larval coloration of Lymantria dispar. The older geneticists would have said that there existed a number of multiple factors for melanin production, several of which show reversal of dominance. Goldschmidt shows that all the factors affect the rate of production of melanın (or other timerelations see later), and that the so-called reversal of dominance occurs only when factors are present, the major part of whose effect in increasing the amount of melanin falls in the larval period; for only then will the original condition of little or no pigment and the final condition of much pigment both be visible, together with all intermediate conditions. Quicker acting genes will hurry the pigment up and make the larva already dark at hatching, slower acting ones will leave it pale right up to pupation.

In Drosophila, dozens of eve-colour and eve-shape genes are known, and their linkage-relations have been ascertained, but the how of their action has scarcely been thought of. Goldschmidt, without pretending to advance more than a formal explanation in terms of physiological genetics, points out that we have in any case to consider the following timereactions: (1) that of the process which determines the differentiation of the eye-rudiment. (2) As with other differentiations, if the eye-determination does not take place by a certain time, other processes are at work which irrevocably determine the cells in some other way—in this case as ordinary epidermis. If (1) is too slow, or (2) too speedy, an eyeless animal is the result. (3) The number of facets depends on the number of cell-divisions taking place in the 'eye-determined' material. Goldschmidt assumes that these cell-divisions are inhibited when the end-products of some process, also with its specific rate, have reached a certain concentration. Changes in the rate of either (1) or (3) will therefore bring about changes in facet-number, as in bar-eye, etc. Finally, he treats the colour-mutations from the same point of view as in his Lymantria larvæ. Now it is clear that many assumptions have been made, some of which, such as (3), may very likely be replaced by better. None the less, it is equally clear that new ways of thinking and new methods of experimental attack are at once suggested by this treatment.

One further example, this time of fact rather than theory. Goldschmidt and his pupils have been able to show that the wing-pigmentation of Lepidoptera is brought about by a curious interrelation of developmental processes The scale rudiments develop at different rates, so that before any pigment exists in the wing, the future pigmentation can be read off as a structural shadow-pattern. The various pigments appear to be produced in the body at different times, and to be shot out into the wings when ready. In the wings they can only be deposited in scales which are at a certain stage of their development: they pass over the rest. Thus the relative rates of scale differentiation and of pigment production both contribute to the actual pattern. Goldschmidt has further been able to show that the melanic form of Lymantria monacha differs from the normal, not in an excess production of melanin, but in a greater development (brought about by a greater rapidity of action of the corresponding genes) of the scales which are in the sensitive stage when the melanin-flood is generated.

In a number of other points Goldschmidt is very suggestive. The phenotypic identity of two conditions, one of which can be shown to have been brought about by altering the organism's environment, the other by altering its genetic constitution, has often been regarded as a grave stumbling-block. Goldschmidt points out, however, that if all visible characters depend upon genecontrolled rates of developmental processes, then this identity is what should be expected.

Valuable as the book is, however, it calls for one or two criticisms and caveats. Goldschmidt has not entirely rid himself of the habit, familiar to students of his earlier works, of providing illustrations which appear to represent curves of accurate quantitative processes without sufficiently warning the reader that they are in reality nothing of the sort, but merely very useful diagrams of possibilities to assist the visualist.

In his earlier works the curves for production of male- and female-determining substances in Lymantria—now copied into all the text-books fell into this category. In the present book, although it is true that warning has often been given, this is by no means always so. theoretical curves for the larval pigmentation of Lymantria (pp. 56-57) are a case in point. That on p. 57 is a chemical impossibility. As a matter of fact, the actual experimental curves obtained (p. 55) can readily be interpreted by adopting two subsidiary hypotheses—that not only the rate of pigment-production is controlled by genes, but also (1) the final density of pigment (equilibriumlevel) obtained, and (2) its time of onset. Both these statements actually hold good for the pigmentation of the eye of Gammarus, and probably in general (Ford and Huxley, Brit. J. Exp. Biol.,

Even where at first sight quantitative accuracy appears to have been attained, this may not turn out to be really the case. Goldschmidt, for example, has a very able discussion on the whole problem of bar-eye in Drosophila (p. 59 et seq.), which at first sight seems demonstrative. Certain assumptions, however, turn out not to be justified: and as a matter of fact, a careful analysis of the figures which I undertook, with the able assistance of Dr. C F. Pantin, has convinced me that Goldschmidt's explanation will not work quantitatively in its present form. On the other hand, I am perfectly convinced that it is on the right general lines, and that if systematic experiments and embryological studies on bar-eye, based on Goldschmidt's ideas, were undertaken, we should soon find ourselves in possession of really accurate quantitative laws bearing on the action of genes in development, and of general application.

This brings me round to my starting-point, and I will merely conclude by recommending the book to the notice of all interested in genetics, developmental physiology, and, indeed, general biology.

J. S. HUXLEY.

### Ectoplasmic Matter.

Clairvoyance and Materialisation: a Record of Experiments. By Dr. Gustave Geley. Translated by Stanley de Brath. Pp. xvi+401+51 plates. (London: T. Fisher Unwin, Ltd. (Ernest Benn, Ltd.), 1927.) 30s. net.

THE late director of the International Metapsychic Institute, Paris, was an enthusiastic exponent of what he and his associates termed 'metapsychic science.' Although this large volume contains nothing new in principle for the student of mediumistic phenomena, the collected results and studies of Dr. Geley's researches mark the end of many decades of controversy as to the reality of the phenomena

It must now be admitted that the various kinds of lucidity and of ectoplasmic formation are facts of experience as actual, though as sporadic, as hypnotism, insanity, or physical deformity. Geley had the qualifications for research work such as are required for observations 'in the field' and for recording the states and behaviour of pathological and mental cases. He was an experienced and capable investigator and his introductory explanations of the conditions requisite for metapsychic research should be read by all those engaged in it. If his precepts were followed there would be fewer than there are at present.

The incentive to devote one's life to these investigations must be either a fixed idea or a temperamental interest in abnormal and degenerate human types. Geley's temperament probably led him into this work, for his only prepossession seems to have been a harmless attachment to a word-"dynamo-psychism"—from which he sought in an earlier work, "From the Unconscious to the Conscious," to evolve a philosophy. In the annals of science it is usually the innovator who enunciates the principles or laws operating in new fields of investigation; others further confirm, elaborate, and tabulate. Geley was not an innovator, but he and other men of science have about completed the survey as regards terminology and classification of evidence and material. There is no scientific or ethical justification, however, for the repetition of these experiments by others. Flourney, Joiré, Schrenck-Notzing, Morselli, Richet, Osty, Geley, and others have established the facts without any religious or spiritualistic implications. Continent spiritism and metapsychics are not synonymous, as the layman, and even some men of science, in Great Britain, believe. These facts can be accepted, just as we acknowledge those guaranteed by specialists in any other research work where the novice and layman do not feel called upon to confirm them by personal investi-They concern chiefly physicians, large numbers of whom have taken part in the experiments described in this and many other books.

Scientific deductions from these facts are now wanted. Nothing new can be learned and no exact knowledge will be obtained regarding the human constitution until the laws governing hypersensible cognition and ectoplasmic matter are formulated. Morselli used analogies from radioactive phenomena to describe certain aspects of ectoplasm. Geley records interesting observations connecting ectoplasmic forms and micro-organisms, especially in regard to the action of light and the production of cold physiological light. Richet suggested that clairvoyance dealing with things was due rather to excessive tactile sensitiveness to emanations with which the article had been charged, unconsciously, by the owner. Others have made the obvious comparisons of radio-telegraphy and television with clairaudience, mental telepathy and clairvoyance

These comparisons are merely suggestive; they may be true, but they are not scientific analogies. Since human nature is a complexity of many kinds of matter, said to be the crown of creation on this earth, we must find analogies that will run right through all the levels of matter, so far known, and correlate these levels in man before the results of metapsychic experiments will have true scientific significance. It is possible that a synthesis of all the sciences relating to man might be achieved could such a scientific correlation be made. A generalisation that includes all the facts of psychic phenomena is necessary, but it must be a principle or law—not a mere word or phrase which may be variously interpreted according to temperament

We know something of the protean possibilities of matter, and this characteristic of ectoplasmic formation is shown by the reproductions of photographs in the book, several of which were published in smaller size in Geley's previous work. plates also include John Tissot's drawing of the lovely apparition named "Katie King" with her Indian guardian, obtained through the mediumship of Eglinton in the early 'seventies, and photographs of the revolting animal and bird forms materialised through the mediumship of Mr. Kluski during experiments conducted by the Polish Society for Psychical Research in 1920. Fifty years of Europe! Could we explain merely this degeneration in the types of materialised forms, the whole subject and its dangers would be under-

Geley inferred from his experiments and believed that there is no essential difference between animals and man; he concluded also that creative genius and mediumship cannot be distinguished in essence, nor can self-conscious clairvoyance and ectoplasmic formation operating during trance. There were no gods, angels, or supermen in his cosmos! Psychodynamic matter is tending to a vague

divinity! What difference this from the 'materialism' for which 'orthodox' science is arraigned? When we leave the solid ground of Nature, unable to understand its operations, word-spinning and idols of the mind masquerade as law

W. W. L

### Lorentz's Theoretical Physics.

Lectures on Theoretical Physics: delivered at the University of Leiden. By H. A. Lorentz. Authorised translation by Dr L. Silberstein and A. P. Trivelli Vol. 1: Aether Theories and Aether Models, edited by Dr. H. Bremekamp. Kinetical Problems, edited by Dr. E. D. Bruins and Dr. J. Reudler Pp. xi+195. (London: Macmillan and Co., Ltd., 1927) 12s 6d net.

URING the last twenty years of his tenure of the chair of theoretical physics at Leyden, Prof. Lorentz delivered short courses of lectures analysing—in the incomparable manner we have learnt to associate with his name-the various aspects of his subject which, during that period, came in for critical examination by the scientific As a result of the energy and enthusiasm of his pupils, these lectures have been preserved in book form, and the present volume is a translation (the originals are in Dutch) of the first of the series. It deals with such subjects as (we quote the titles of the separate lectures) aberration of light, mechanical ether theories; Kelvin's model of the ether; attraction and repulsion of pulsating spheres; inner friction and sliding, treated hydrodynamically; friction and sliding, treated kinetically; Knudsen's investigations on rarefied gases; remarks on Lesage's theory of gravitation: friction and heat conduction in the propagation of sound, kinetic theory of systems of electrons. Richardson's investigations; vacuum contact of plates of different metals; problems in which the motion of electrons plays a part

As these titles suggest, the first section deals with the possibilities and probable hidden secrets of a mechanical radiation-carrying ether and is on lines which were familiar to all physicists twenty years ago. These discussions are now somewhat out of fashion, although a recent attempt—arising out of a complete misunderstanding of certain positive results obtained by Miller in a repetition of the Michelson-Morley experiment—has been made to revive interest in them. They lead almost inevitably to the conclusion which we find here stated so concisely by Lorentz. "To a certain extent these theories are successful, but it must be

admitted that they give but little satisfaction." Actually they can be made more impressive than Lorentz shows, because so many of the difficulties so clearly discussed by him really arise from an attempt to make the ethers explain not only themselves but also matter as well. If we adopt the more reasonable attitude and accept matter as being something over and above the ether—the ribbon tying the knots-then, as Larmor so ably shows in his review of these problems,1 we are not involved in a large number of the paradoxes which otherwise present themselves. Even then, however, it is difficult to avoid the troubles involved mainly in the possibility of the coexistence of two independent statical conditions—electric and magnetic-so we cannot but subscribe to Lorentz's final conclusion

In the other sections of his lectures Lorentz deals with less speculative problems But his treatment of such familiar matters as viscosity and internal friction, the flow of rarefied gases through tubes and orifices, the propagation of sound in gases, and certain problems in the electron theory of metals, are exceptionally lucid and satisfying. Like the rest of Lorentz's work, it combines a most exceptional blend of physical intuition and analytical skill which carries conviction with it at every stage. His concluding lectures on the statistical problems of the electron theory of metals contain an elaboration of an important point which should be noted. The usual simpler forms of the theory lead to a number for the electron content which is at least 1000 times too large. If, however, an internal potential for each electron and characteristic of the metal-suggested by Lorentz in his original memoirs on this subject—is included, this fundamental difficulty disappears and so also do some of the difficulties in the further development of the subject not dealt with by Lorentz in these lectures.

The translators—and publishers—have carried out their task very satisfactorily. Here and there, owing to an obviously too strict adherence to the order of words in the original, an awkwardly constructed sentence holds up the reader, and a few words like parallelepipedon and generatrix are given an unfamiliar—but not misleading—form. These slight blemishes are, however, few and far between, and the book is on the whole worthy of the author whose name appears on the outside; it can in consequence be specially commended to those who are—and were—interested in the subjects with which it deals. G. H. L.

### Our Bookshelf.

The Principles and Practice of Mine Ventilation · being a Treatise on Modern Methods of Mine Ventilation and Machinery, with a Consideration of Deep Mine Problems, Explosions, Fires, Rescue and Recovery Work, and Cognate Subjects By Prof. David Penman and Dr. J. S Penman (London Pp. viii + 303 (London Co, Ltd, 1927.) 21s net. Charles Griffin and

Ventilation of Mines By Prof. Walter S. Weeks Pp x+228. (New York: McGraw-Hill Book Co, Inc; London: McGraw-Hill Publishing Co, Ltd, 1926) 15s net.

For some time past considerable attention has been given to the principles of mme ventilation; institutions, committees, and individuals have been hard at work for some years trying to render our knowledge of this complex subject more accurate, and at the same time to express that knowledge by means of readily intelligible formulæ. It is beginning to be generally admitted that no single formula can quite accurately express all the facts, but there are strong hopes that a reasonably simple formula giving results near enough for all practical purposes may be the outcome. The two books now before us are evidence of the widespread interest that is being taken in the subject; both are fairly satisfactory works within their own spheres, but, curiously enough, these spheres are entirely different. The British book is addressed essentially to students, the American book essentially to mining engineers. Thus it is that in the former it is thought necessary to give such elementary information as that "inversely means in the opposite direction," and to conclude each chapter with a series of questions, adapted apparently to the capacity of elementary students, whilst in the latter attempts are made to discuss such advanced problems as the economics of ventilation, and to solve such problems as, for example, "What is the most economic size of an airway under given conditions?" It must unfortunately be admitted that the author's solution of the problem is neither complete nor correct, but the fact that he attempts to solve it indicates the stage to which the work is carried.

Necessarily there is very much that is common to the two books, and indeed there is a mass of material available which may fairly be said to be the common property of all mining engineers interested in the subject. The British work, however, devotes much more attention to the details of fan construction, which the American writer takes for granted; the former is aware that students must be taught the construction of different types of fan on the market, but the latter assumes that the engineer will be sufficiently familiar with these to require but little additional information. Furthermore, it may be pointed out that whilst the British work practically limits itself to the consideration of the ventilation of collieries, the American work, hailing as it does from California, naturally devotes as much attention to the ventilation of metalliferous mines as to that of collieries. The weakest point

 $<sup>^{\</sup>mbox{\tiny 1}}$  "Æther and Matter." This book should be read in conjunction with these lectures of Lorentz.

in both books is their failure to treat adequately the practically important subject of the testing of fans, although, as might be supposed, this is rather more fully considered by the American than by the British author.

Geschichte der Physik. Von Edmund Hoppe. Pp. viii +536. (Braunschweig Friedr. Vieweg und Sohn A.-G., 1926.) 30 gold marks.

WE can scarcely imagine a more difficult task than the writing of a trustworthy and adequate history of physics. The field is so extensive and the work of reference so enormous that we can readily appreciate that Prof. Hoppe has spent several decades on his undertaking, and in this admirable book he has given the pith of his researches. The treatment is brief but delightfully clear, and in these days of turmoil, when the spirit of revolution has invaded even the realms of physics, it is refreshing to read of the gradual evolution of ideas, based on experiment, from the time of the Greeks through the Middle Ages to the end of last century.

The greater part of the book, almost five hundred pages, is devoted to physics of the Neuzeit, beginning with the close of the sixteenth century, and the book deals in turn with mechanics, heat, optics, and electricity and magnetism, whereby each section is prefaced by a brief statement of the earlier work in that branch of the subject. No attempt is made to deal with the discoveries of the present century, but the continuity of development of the subject is amply portrayed, and we are made to feel that there would have been no 'new physics' but for the classical physics which preceded it. In these days of relativity and quanta, students are perhaps inclined to look askance at the earlier work, and yet much of the remarkable development of our own day is a direct outcome of the discoveries of the end of last century and earlier.

The numerous and comprehensive references to the literature in the text are a valuable feature of the book. The omission of the initials before the names of authors has in a few cases resulted in a certain amount of confusion. Thus in the index (p. 524) there are two entries under the name of Rutherford, but they refer to different persons. The first is the Rutherford (1753–1819) of the maximum and minimum thermometer, whereas the secord is Sir Ernest Rutherford. On p. 177 the names Negrette and Zumbra should surely be Negretti and Zambra, and on p. 505 few people will realise that the 'de Smolan' referred to is in reality Smoluchowski.

The Wilderness of Sinai: a Record of Two Years' Recent Exploration. By H. J. Llewellyn Beadnell. With a Foreword by Dr. D. G. Hogarth. Pp. xvi+180+16 plates. (London: Edward Arnold and Co., 1927.) 10s 6d. net.

Mr. H. J. L. BEADNELL, during his service in the Geological Survey of Egypt, enjoyed the privilege of two years' survey of the mountains of Sinai. In this book he gives an interesting narrative of his experiences and records, his observations on the country and people, and especially on its

geology and physical geography. The country is of popular interest from its connexion with the wanderings of the Children of Israel on their way from Egypt to Palestine, and the author's account indicates that the physical conditions of this region were the same then as now, and that no large body of people could have crossed the mountains of southern Sinai. Moses probably followed a route across the northern plains.

The scientific interest of Sinai depends largely on the light it throws on the nature of the gulfs on either side. According to Dr Ball, of the Egyptian Geological Survey, the Gulf of Suez is a normal valley of erosion and was excavated by a river along the summit of an arch. According to the alternative explanation, the Gulf is a rift valley due to the subsidence of a strip of country between parallel faults; the actual dislocation of the rocks may be seen from passing steamers, but according to Dr. Ball these disturbances are merely landships. Mr Beadnell declares that the evidence that the Gulf of Suez is a fault-made valley is irresistible. His new information also supports the conclusion drawn from W. F. Holland's map of 1869—to which there is no reference in the text—that the angular parallel-sided valleys of Sinaı are also tectonic and are due to the rifting of the country by the earth movements that made the adjacent gulfs.

The photographic illustrations are of especial interest, for they show the topography and structure with almost diagrammatic clearness. An interesting introduction by Dr Hogarth refers to the historic associations and attractions of this country which he describes as looking, when seen from the eastern (fulf, as alluring as a Gustav Doré vision of hell.

A Year among the Persians: Impressions as to the Life, Character, and Thought of the People of Persia, received during Twelve Months' Residence in that Country in the Years 1887-1888. By Edward Granville Browne. With a Memoir by Sir E. Denison Ross. New edition. Pp. xxii +650. (Cambridge: At the University Press, 1926) 25s. net.

SIR DENISON Ross, who contributes a memoir of the author to this volume, points out that it is a remarkable fact that one of the most fascinating and instructive books of travel ever written should have remained out-of-print for a long period of years. Not only did Browne's valuable work cover a very interesting and important period in the political relations of East and West, as well as in the internal history of Persia, but also he covered ground in his journey which is still very little known. Where it is more familiar, a comparison with present-day conditions, especially, for example, in Asiatic Turkey, is highly instructive.

Browne wrote with a peculiar charm, his style was lively, and, thanks to his marvellous memory, always realistic. The fascination which Persia, and its literature and philosophy, held for him ensured a sympathy with his subject which he never fails to pass on to his readers. Sir Denison

Ross's memoir, which is instinct with the intimate touch of a friendship of long standing, is a faithful picture of a personality full of charm, if not without its peculiarities, and a life of disinterested devotion to the advancement of learning. The thanks of the reading public are due to the Cambridge University Press for their re-issue of a notable and enduring work in a form which is as handsome as it deserves.

(1) Myth in Primitive Psychology By Dr. Bronslaw Malinowski. (Psyche Miniatures: General Series, No. 6) Pp 128 2s 6d. net (2) Fee, Fi, Fo, Fum: or, The Giants in England. By H J. Massingham. (Psyche Miniatures: General Series, No. 5.) Pp 175+4 plates 2s. 6d. net (London Kegan Paul and Co, Ltd., 1926.)

Of these two volumes in this attractively got up little series, Dr Malinowski's contribution is written on lines with which what may be called his 'occasional' writings have made us familiar. It is his method to take some aspect of primitive culture—magic, jurisprudence, or, as on this occasion, myth—and, instead of dealing with it in vacuo, putting it in its context as a live element in the everyday life of primitive man as he himself has known him. In this case he shows what the legend, tradition, or story means to the native of the Trobriands by telling us not only of the matter with which it deals, but also of the manner it is told, the occasion, and by whom. It is, as he says, a reality lived, a hard-worked active force, a pragmatic charter of primitive faith and moral wisdom.

Mr Massingham, on the other hand, belongs to another school and deals with matter that is no longer alive except as the stuff from which theory is made. His giants and dragons carved in the English hill-sides with their traditions and the stories of Arthur, the heroes of the Mabinogion and of Merlin, are the relics of a forgotten age which has to be painfully pieced together in a process of reconstruction. The author being a whole-hearted 'diffusionist,' this reconstruction is based on an interpretation of the material in terms of the 'megalithic culture' and the 'children of the sun' and their derivation from Egypt.

Naturalist's Guide to the Americas. Prepared by the Committee on the Preservation of Natural Conditions of the Ecological Society of America, with assistance from numerous Organisations and Individuals. Assembled and edited by the Chairman, Victor E. Shelford. Pp. xv+761+16 plates. (Baltimore, Md.: Williams and Wilkins Co.; London: Baillière, Tindall and Cox, 1926.) 45s. net.

This important volume, which indicates the strength of the movement towards the ecological study of the problems of biology in America, will be an invaluable tool in the establishing of Nature reserves from the Amazon to the Arctic Circle. As a result of many years' labour, an enthusiastic band of scientific workers has catalogued all preserved and preservable areas in North America in which natural conditions persist, the ultimate

object being the reservation of all such areas in order that there, so far as possible, the primitive balance of Nature may be maintained. preliminary study indicates, for each of the United States and Canadian provinces, the leading physical features, meteorological conditions, biological zones, summarises the associated flora and fauna, and mentions the areas suitable for Nature reserves. An introductory section discusses from many points of view the uses, values, and management of natural areas, and an effort is made to trace the original biota of North America. Ecological study demands a much more intensive investigation than could be compassed in this extensive monograph, but it sets the framework within which the future worker must build in detail.

Ancient Persia and Iranian Civilisation. By Clément Huart Translated by M. R. Dobie. (The History of Civilisation Series.) Pp xix + 249 + 4 plates (London Kegan Paul and Co, Ltd.; New York Alfred A. Knopf, 1927.) 12s. 6d. net.

MR HUART'S book on ancient Persia contains a very good account of the cultural history of old A vivid picture of the country, and an account of the scripts in which Persian texts have been written, is followed by the history of the three great dynasties, the Achæmenids, Arsacids, and the Sassanids. The real value of the book consists in the excellent analyses of the cultural data referring to each epoch; the social organisation, the religious cults and beliefs, and the artistic productions. The powerful character sketches of the various monarchs and heroes, starting with the legendary Cyrus, receive new life from the cultural background in which they are set. The author makes us feel the scenery, through his descriptions drawn from personal experience and by the many pictures which enliven the book The chronological table and bibliography add to the value of the book, while the excellent index facilitates its use for reference.

Prehistoric Man. Written and Illustrated by Keith Henderson. (The Simple Guide Series.) Pp xv+276. (London: Chatto and Windus, 1927) 7s. 6d net.

As a stimulating introduction to prehistoric man, his haunts, habits, and arts of life, this volume in "The Simple Guide Series" will prove very useful. It is written vividly and without any surface pedantry though it condenses a good deal of information into a small space. It will succeed in sweeping from the picture of our stone age ancestors some of the dry dust with which the learning of specialists, as well as the centuries, have covered it. It leads us from lemurs, monkeys, and apes up to the man of the bronze age. Needless to say, no specialist in prehistory will completely agree with any other author's conclusions, whether these be put in popular or learned language, but, on the whole, Mr. Henderson succeeds in giving a fair and wellbalanced summary of the sound and established results of modern prehistoric science.

### Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

### Experiments on Sex in Rust Fungi.

The phenomenon of heterothallism (the separation of sex in different individuals) is known to occur in the Phycomycetes (Mucor), in the Ascomycetes (Ascobolus, Penicillium), in a large number of Hymenomycetes (mushrooms and toadstools), and in the Smut fungi. Therefore the question arises: Does heterothallism occur in the Rust fungi? An attempt to solve this problem, which is of considerable theoretical and perhaps practical interest, has been made by the author by sowing the sporidia of Puccinia helianthi on leaves of young Sunflower plants and observing whether or not aecia are produced: (1) when a single sporidium is sown by itself, and (2) when two sporidia are sown close together.

Sporidia produced on promycelia developed by teleutospores attached to old dead Sunflower leaves were allowed to fall on to the green leaves of young Sunflower plants in such a way that, as a rule, they settled at some distance apart but so that, sometimes, two sporidia settled close to one another. The sporidia were not actually seen on a leaf after they had settled there. When a sporidium infects a leaf, the pustule at its first appearance is a tiny reddish dot no larger than the dot of an i in this letter. Altogether more than 1200 monosporidial and about 200 bisporidial pustules have been under observation.

The facts observed during the investigation upon Puccinia helianthi may be thus summarised.

A. Within two weeks the following happens, and usually within three weeks nothing more happens:

1. Each isolated pustule derived from a monosportial infection usually becomes 0.6–1.2 cm. in diameter and develops pycnia which excrete nectar, but it does not give rise to any aecia (Fig. I, pustule to the left). The pycnia appear about 8 days after the sowing of the sportia.

2. In a compound pustule formed by the coalescence of two simple pustules, each simple pustule owing its origin to a monosporidial infection, when the distance between the two centres of infection is not more than about 1 mm., either: (a) aecia appear in the compound pustule 10-11 days after the sowing of the spores (Fig. 1, pustule to the right), or (b) no aecia appear.

3. When two simple pustules, each derived from a monosporidial infection, arise near to one another, coalesce, and produce aecia: the nearer they are and the sconer they coalesce, the sconer are aecia developed; while the farther apart they are and the later they coalesce, the later are aecia developed.

4. Where in compound pustules, each derived from two monosporidial infections, the centres of infection are not more than 2 mm. apart, the number of compound pustules producing aecia is about 50 per cent. of the whole. This conclusion is based on observations made upon about 175 compound pustules.

B. At the end of three weeks or more rarely less, in respect to pustules both simple and compound which hitherto have not produced any aecia, the following happens:

1. A majority of the pustules (about 60 per cent.) never produce aecia, even when the pustules persist for so long as six weeks.

2. A minority of the pustules (about 40 per cent.)

produce aecia of normal form and colour. In at least some of these aecia the aeciospores are uninucleate, whereas in aecia produced in a compound pustule 10-11 days after the sowing of the sporidia (vide A, 2, above) the aeciospores are all binucleate.

The following theoretical deductions may be drawn

from the series of facts just recorded.

1. Since pycnospores appear on every mycelium of monosporidial origin, it is clear that, if the pycnospores are really nothing but non-functional male gametes (spermatia), Puccinia helianthi is not dioecious. In other words, the monosporidial mycelia of the Sunflower Rust fungus are not of two kinds: (a) male, bearing spermatia, and (b) female, not bearing spermatia.

2. The pycnospores are not functionless male gametes but are simply conidia corresponding to the uninucleate oidia which appear on the monosporous

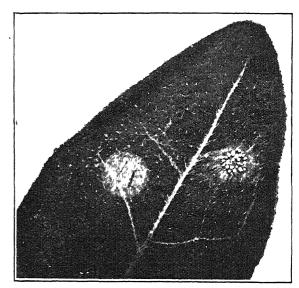

Fig. 1—Underside of a Sunflower leaf which was inoculated on its upper side with sporidia of Puccinu helianthi, photographed twenty-three days after inoculation. To the left, a pustule derived from a monosporidial mycelium showing absence of aceta (it had numerous pycnia on its upper side). To the right, a compound pustule formed by the coalescence of two simple pustules each derived from a monosporidial mycelium. The compound pustule has developed typical aceta. Magnified two and one-half times the natural size

mycelia of such heterothallic Hymenomycetes as Coprinus lagopus, C. niveus, Strophana semiglobata, and Collybia velutipes.

3. The pyenospores produced on (+) monosporidial mycelia are (+) in their sexual nature, while pyenospores produced on (-) monosporidial mycelia are (-) in their sexual nature.

4. The sporidia are unisexual and produce unisexual mycelia. The (+) and (-) monosporidial mycelia, and therefore the (+) and (-) sporidia from which they originate, appear to be about equal in numbers. This suggests that segregation of the (+) and (-) factors takes place in the promycelium during nuclear division in the same manner as it takes place in the basidium of Coprinus Rostrupianus and of C. radians (=C. domesticus).

5. When two sporidia of opposite sex, (+) and (-), are sown close together on a Sunflower leaf so that the pustules arising from the two infections soon coalesce, the two monosporous mycelia come into contact, fuse together, and give rise to normal binucleate aeciospores, each conjugate pair of nuclei formed in the spore-bed consisting of a (+) and of a (-) nucleus

No. 3012, Vol. 120]

derived from a (+) and from a (-) mycelium respectively.

6. When two sporidia of the same sex—that is, two (+) sporidia or two (-) sporidia—are sown close together on a Sunflower leaf so that the two pustules arising from the two infections soon coalesce, the two monosporous mycelia come into contact but do not interact sexually, and therefore do not give rise to any

7. The belated aecia, which appear at the end of about three weeks on pustules of monosporidial origin or on pustules of bisporidial origin where presumably the two sporidia are of one and the same sex, probably arise without any hyphal fusions.

8. In any heterothallic Rust fungus that behaves like Puccinia helianthi there is a possibility of two strains of the same species being crossed by means of the union of their monosporidial mycelia within the tissues of one and the same host-plant.

A few experiments have already been made by sowing the sporidia of *Puccinia graminis* on the leaves of the Barberry. The results, so far as they have gone, appear to be similar to those already described for Puccinia helianthi.

In conclusion, I desire to acknowledge valuable assistance derived from consultation with Prof. A. H. Reginald Buller. J. H. CRAIGIE.

The Dominion Rust Research Laboratory, Winnipeg, May 25.

### Eigenvalues and Whittaker's Function.

Among those who are trying to acquire a general acquaintance with Schrodinger's wave-mechanics there must be many who find their mathematical equipment insufficient to follow his first great problem to determine the eigenvalues and eigenfunctions for the hydrogen atom I do not think it is generally realised that Schrodinger's differential equation for this problem is one which is fully treated in a standard text-book, Whittaker and Watson's "Modern Analysis," Chapter xvi. (I quote from the second Analysis," Chapter xvi. (I quote from the second edition) It would seem that advantage may be taken of this to make the treatment easier for English readers. I realise that the following is only a slight redressing of Schrodinger's method; but I think it will be intelligible to some who have been unable to appreciate the original, and that it gives a useful idea of the genesis of eigenvalues.

Having set  $\psi = \chi(r)S_n$ , where  $S_n$  is a spherical harmonic of integral order n, Schrödinger shows that his wave-equation gives:

$$\frac{d^2\chi}{dr^2} + \frac{2}{r}\frac{d\chi}{dr} + \left(\frac{8\pi^2 mE}{h^2} + \frac{8\pi^2 me^2}{h^2r} - \frac{n(n+1)}{r^2}\right)\chi = 0, \quad (1)$$

and he seeks solutions which shall be finite for all

values of 
$$r$$
 including 0 and  $\infty$ .

Writing  $u = r\chi$ , this becomes:
$$\frac{d^2u}{dr^2} + \left(\frac{8\pi^2 mE}{h^2} + \frac{8\pi^2 me^2}{h^2r} - \frac{n(n+1)}{r^2}\right)u = 0.$$

Change the unit of r by writing

$$r_1 = r \sqrt{\left(\frac{-32\pi^2 mE}{h^2}\right)}.$$

The equation then takes the standard form:

$$\frac{d^2u}{dr_1^2} + \left( -\frac{1}{4} + \frac{l}{r_1} + \frac{\frac{1}{4} - (n + \frac{1}{2})^2}{r_1^2} \right) u = 0, \qquad (2)$$

where

$$l = \sqrt{\left(\frac{-2\pi^2 m e^4}{h^2 E}\right)}. \qquad . \qquad . \qquad (3)$$

The general solution of (2) is (W. and W., § 16-31):  $u = AW_{l,n+\frac{1}{2}}(r_1) + BW_{-l,n+\frac{1}{2}}(r_1),$ 

where W is Whittaker's function. It is here sufficient to consider the solution  $u = W_{l,n+1}(r_1)$ . The asymptotic expansion for W (loc cit § 16.3) gives:

We see at once that u vanishes at  $r_1 = \infty$ , and the only danger of divergence is at  $r_1 = 0$ . We notice further that the cases in which

 $n+\frac{1}{2}=l-\frac{1}{2}, l-\frac{2}{2}, l-\frac{5}{2}, \ldots$ 

ie when

$$l = n + 1, \quad n + 2, \quad n + 3, \dots$$
 (5)

present an exceptional feature. For if  $n + \frac{1}{2} = l - p + \frac{1}{2}$ , the last factor in the numerator of  $1/r_1^p$  vanishes, and this zero factor is repeated in every succeeding term. The series thus terminates, and the expansion accordingly becomes exact. The final term in u is then  $e^{-\frac{1}{2}r_i}r_1l^{-p+1}$  or  $e^{-\frac{1}{2}r_i}r_1^{n+1}$ , so that the final term in  $\chi$  is  $e^{-\frac{1}{2}r_i}r_1^{n}$ . Hence  $\chi$  is finite at the origin, and the values (5) are the required eigenvalues. The corresponding energy values -E are then given by (3). The expression (4) gives the eigenfunctions.

A. S. Eddington.

### Use of Carbon Dioxide in a Mercury Interrupter.

It is customary to use coal gas as a dielectric in the mercury interrupter and it has generally been found to be quite satisfactory in action. There are, however, places in the country where coal gas is not available, and the following experiments were undertaken with the view of examining the possibility of employing carbonic acid gas used in connexion with X-ray work carried out in hospitals at such places.

Carbonic acid gas is available in cylinders at many places, and, being an inert gas, it naturally suggests itself as a very useful substitute for coal gas. It is, however, necessary to examine the efficiency of the interrupter using carbonic acid gas by comparing it with that using coal gas and also hydrogen. Since the most important function of the dielectric is to extinguish the flame, it is necessary to examine its action when it is employed in an interrupter in two different ca. stances; in one case, when the primary of the induction coil is connected up straight to the source of electric power which gives just sufficient potential difference in the primary to obtain the desired E M.F. in the secondary, and in the second case, when the primary draws current from the supply main's through a large rheostat which regulates the current in the primary to yield the desired E.M.F. in the secondary.

It is obvious that the two cases are different. In the first case, the sparking inside the interrupter is considerably less than in the second case, where the whole potential difference of the supply mains is

effective in producing the spark at the break.

The experimental work for each gas was consequently divided up into two parts. In the first part the power to the primary was supplied from a potentiometer device connected up to the 230 volts D.C. mains, and in the second, the primary was connected to the mains through a rheostat.

The length of the spark-gap was taken to indicate the magnitude of the voltage generated in the secondary. The current drawn by the primary could be read off from an ammeter placed in series with it (see Fig. 1). The same experiments were repeated with an X-ray tube connected up with the secondary with a milliammeter in series (see Fig. 2).

In the second part of the experiment the primary

and the interrupter were connected up to the main supply of 230 volts and the current was suitably cut down by means of an adjustable rheostat and measured by means of an ammeter (see Fig. 3). The same experiments were then repeated, using an X-ray tube (see Fig. 4).

It can be seen from the results that in either case, The difference between the working of the gas-

when hydrogen or carbonic acid gas is used, the efficiency of the interrupter is greater than when coal gas is used. Hydrogen gives the longest sparkgap, that is, the highest value of the secondary E.M.F. with the smallest potential difference in the primary. mercury-interrupter using coal gas and carbonic acid gas is less in the case when the full 230 volts are allowed to play across the break than when the potential difference at that point is carefully adjusted

These results should prove useful in places where coal gas is not available but where carbonic acid gas can be carried in steel containers.

### Biological Fact and Theory.

"I've often thought that headstrong youths Of decent education, Determine all-important truths, With strange precipitation, ("The Periwinkle Girl," W. S. Gilbert's "Bab Ballads.")

> If, instead of attributing to me a certain skill in controversy, Prof. J. S. Dunkerley (July 2, p. 12) had paid my intelligence the greater compliment of reading carefully what I had written, I might have been saved from begging for more space in which to refute what I believe are mistaken ideas. I had hoped that I had so expressed myself that my meaning was quite clear even to the casual reader. As Prof. Dunkerley has missed all my important points, I have apparently failed in his case and may have done so in others. May I give a variant of what is perhaps the most important argument I have used, which I hope will be intelligible to

> The very evidence that favours the hypothesis that units representing Mendelian characters are present in individual chromosomes, is absolutely against the probability of such units representing those characters that are common to all individuals comprised in an indefinite number of successive generations in a large group of organ-The 'Neo-Mendelian theory' isms. assumes that all characters are dependent upon 'genes' and that all genes' are units arranged in regu-

lar order, each in its particular chromosome. The cell phenomena that precede fertilisation, according to presently accepted observations, seem to provide for an alternative distribution of the chromosomes to the daughter cells. As, however, only half the somatic number of whole chromosomes go to each sperm or mature ovum, only a proportion of the organisms of the next generation can contain any given paternal or maternal chromosome. This agrees with the Mendelian breeding experiments, but is incompatible with the reappearance of those characters common to all individuals in successive generations, if every character is represented by a unit which has an assigned place in a particular chromosome. The hypothesis that the capacity for reproducing recent variations is conveyed by the chromosomes, while common racial characters are dependent upon something else in the cell, does not appear so utterly incompatible with recorded breeding experiments and cytological observations as the 'Neo-Mendelian theory' of 'genes.' The Mendelian characters are probably recent variations and may be represented in the chromosomes; racial characters

to the minimum to yield the required E.M.F. in the secondary as indicated by the length of the spark-gap. The curve for carbonic acid gas being lower than the curve for coal gas, it is also clear that it would be more economical to use carbonic acid gas, since to obtain equal E.M.F.'s in the secondary, less electric power is required in the primary.

There is next the question of safety in handling the Carbonic acid gas, being heavier than air, is capable of easily displacing the air from the interrupter, and the fact that the interrupter is full of the gas can be easily tested. The gas itself is of course harmless.

Further points in connexion with this gas are that it has no action on the electrodes and the gas remains unaltered after long use. In order to ascertain that the gas remained unaffected by constant sparkings inside the interrupter, the gas was tested after half an hour's continuous run. Samples of the gas-filling were drawn off from the interrupter, and on analysing them it was found that the gas had not undergone any appreciable change. The electrodes also were not affected.

cannot. If Prof. Dunkerley will again read my previous letters to Nature (Jan. 29 and June 4) he will realise that the 'exceptions' to the 'Neo-Mendelian' views of the functions of the chromosomes were given in the hope of elucidating this interpretation of generally accepted observations, and not with the incomprehensible objective which he attributes to me.

Prof. Dunkerley writes: "The transmission of paternal characters by the spermatozoon is not denied by Dr. Walker, and if he doubts the transmission of these characters in some way through the chromatin material of the male sperm cell, there is very little left in the sperm." This is an example of those loose methods of thought and expression which have led to much misunderstanding of biological problems. What are "the paternal characters"? Are those peculiar to the male parent only implied? Godlewski fertilised enucleated eggs of sea-urchins with the sperms of crinoids, and these developed into gastrulæ possessing only maternal characters, though apparently all the chromosomes present were of paternal origin (Archiv fur Entwicklungsmechanik, Bd. 20; 1906). There are records of many other experiments bearing upon this point (Driesch, H., Arch. f. Entwick., Bd. 16; 1903. Boveri, Th., ibid. Loeb, J., Arch. f. d. gesam. Physiol., Bd. 99; 1903. Bataillon, E., Arch. d. Zool. Expér., Tom. 6; 1910).

I do doubt the transmission of paternal or any other characters in any way by the chromatin of any cell, even including the "male sperm cell," whatever that may be. So long ago as 1907 ("Essentials of Cytology") I pointed out that in all probability the chromatin is merely a secretion of the linin, and that if there are permanent and individual constituents of the cell handed on from one generation to another, they are to be found in the linin and not in the chromatin. Doubtless the little regular rows of chromatin granules of the cytological preparation are tempting to the 'Neo-Mendelian,' but the evidence against their permanent nature is strong.

I fail to see the point of the remark as to the proportion of the sperm left when the chromatin is eliminated.

Having admitted the difficulty of imagining all or half the potentialities "for the development of an animal" being contained in the "microscopic spermatozoon," Prof. Dunkerley goes on: "Then is it much more difficult to believe that these potentialities are arranged in some sort of order in the individual chromosomes?"

"I can't believe that!" said Alice.

"Can't you?" the Queen said in a pitying tone.
"Try again: draw a long breath, and shut your eyes."... "I dare say you haven't had much practice," said the Queen. "When I was your age, I always did it for half an hour a day. Why, sometimes I've believed as many as six impossible things before breakfast." ("Through the Looking-Glass," Lewis Carroll. London: Macmillan and Co., 1873.)

University of Liverpool, July 3.

## On X-ray Diffraction Patterns from Liquids and Colloidal Gels.

On account of the present great interest in the interpretation of X-ray patterns for amorphous substances (broad haloes) it seems desirable to present in a preliminary way a few of the observations made in the present writer's laboratory. These tend to show that very important information of practical bearing can be obtained on rubber and its substitutes, introcellulose, gelatine, linseed oil, china wood oil, resins,

varmshes, etc In all cases the films have been measured photometrically so that on the curves the exact centres of the broad bands are easily located.

119

For unstretched rubber latex films the spacings calculated by the Ehrenfest formula  $(a = 7.72 \, \lambda/4\pi)$  $\sin \theta$ , where  $2\theta$  is the diffraction angle) from the two principal rings (second order faint rings appear in addition) are 6.03 Å.U. and 14 76 Å.U., in fair agreement with Hauser and Rosbaud (Kautschuk, Jan. 1927, p. 17). When, however, the rubber is very carefully purified by a process of fractional solution and evacuation to constant weight, the spacings are 5.97 Å.U. and 11 15 Å.U., a profound change in the inner ring. Intermediate values up to 14 76 Å.U. have been observed with solvent swelling. On account of the excellent proof by Zernicke and Prins (Zeit Physik, 41, 184; 1927) that the broad rings are indicative of the natural distance of nearest approach of molecules, the classical Bragg formula  $n\lambda = 2d \sin \theta$  seems preferable to the Ehrenfest expression, which was derived for regular spacing of atoms within molecules.

With nitrocellulose of the same composition the following quantitative results are typical for the spacings of the inner and outer rings respectively

calculated by the Bragg formula:

	Fresh.	Aged (light).	(heat).
Untreated, dry	$\begin{cases} 7 \ 18 \ \text{Å U.} \\ 4 \ 02 \end{cases}$	{7 17 Å.U. 4 05	{6 98 Å.U. 3.92
Dry, residual solvent present	${9\ 30} \atop {4\ 47}$	${9\ 32} \ 4\ 47$	${786} \ 431$
Oil softener added	${734} \ 4.31$	$\{\overline{\frac{1}{439}}$	$\{\frac{1}{439}$

The swelling or combination of molecules with solvent or oil has a much greater effect than aging, even though the film may become very brittle.

Contrary to the results of Katz (Zevt. physik. Chem., 125, 321; 1927), distinct though usually small differences in spacings are observed with china wood oil and linseed oil during polymerisation and drying. The following remarkable results on china wood oil were obtained by careful measurement of the photometric curves; they are expressed as percentage change related to the spacings of the raw liquid oil calculated by the Bragg formula:

The prepared liquid in this case consisted of china wood oil heated with Venice turpentine and thinned with pure turpentine. The film dries with a crystalline finish, which is, however, only a pseudo-crystalline wrinkled skin. The increase in spacings (decrease in ring diameters) in every case, including drying, over those of the raw oil is remarkable. Combination with solvent molecules and polymerisation are both definitely indicated. No indication has been found in these patterns of long spacings such as are obtained with solid carbon chain compounds, and such as have been observed for liquid primary normal alcohols by Stewart and Morrow (Proc. Nat. Acad. Sci., 13, 222; 1927). It is possible that diffraction rings corresponding to these long spacings may be so close to the central direct-beam trace on the photographic films that they are not defined. This is particularly true where molybdenum Karays have been used instead of rays from a copper target.

Similar results have been obtained with cumar, resins, varnishes, etc. In all cases it is clear that the 'amorphous' ring diagrams may yield very important

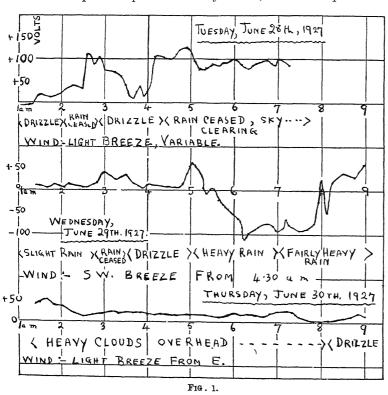

theoretical and practical results in terms of fundamental space array of molecules or aggregates acting as units, polymerisation, the swelling of gels, and changes during aging. X-ray science has apparently reached the stage wherein it may analyse all matter in any form whatsoever.

### Potentials during the Solar Eclipse.

OWING to adverse weather conditions we were unable to take any photographs of the solar eclipse at Bangor. Certain other observations which were made may be of interest. A thermometer mounted on a stand in the open and viewed through a telescope recorded a drop in temperature of only 0° 5 C., the

actual temperature at the time of totality being  $8^{\circ}\text{-}5~\mathrm{C}.$ 

Readings were taken by the water-drop method of the variation of the potential at a point 215 cm. above the ground before, during, and after the eclipse. The potentials recorded on June 28, 29, and 30 are shown in the accompanying diagram (Fig. 1). It will be noticed that during the eclipse there was a change from a positive to a negative potential, this change being probably due to the heavy rain which fell at the time.

The darkness and fall of temperature during totality were not so marked as they would have been had there been no cloud, and the whole phenomenon was disappointing in this part of the country.

## Series in the First Spark Spectrum of Tin.

Following the work of one of the authors on regularities in the spark spectrum of tin (Sn III, Proc. Phy. Soc., 39, 161; 1927; and Sn IV, in the course of publication), the spectrum of the element in the singly-ionised stage (Sn II) has been investigated.

According to the theory of spectra recently developed by Hund, the first spark spectrum of tin must arise from transitions of one electron successively through the  $O_2$ ,  $P_1$ ,  $O_3$ ,  $P_2$ ,  $Q_1$ ,  $Q_4$ ... shells which result respectively in the usual doublet terms in the order of value,  $1^2P$ ,  $1^2S$ ,  $1^2D$ ,  $2^2P$ ,  $2^2S$ ,  $1^2F$ , etc. All these terms have been found, the largest being  $1^2P_1 = 117684$ , giving the second ionisation potential of tin to be about  $14\cdot 5$  volts. Besides these, the configuration of

Besides these, the configuration of one  $O_1$  and two  $O_2$  electrons gives  ${}^4\bar{P}, a^2D, {}^2P, a^2S$  terms. Combination pairs between this  $a^2D$  term (found to be identical with the  $x_{12}$  terms mentioned in the paper referred to above) and the regular  ${}^2P$  and  ${}^2F$  terms are detected, the latter forming a characteristic series, very prominently seen in the spark spectrum of the element, and there is probably an indication of the existence of the  ${}^4\bar{P}$  term also. As a result of the analysis, about thirty lines of the first spark spectrum of the element have been classified, which include a large number of the strong lines observed in the ordinary spark and the vacuum arc in the visible and the fluorite region.

The first doublet P separation is found to be 4247 cm.<sup>-1</sup> which is in agreement with the value inferred from the probable limiting difference  $\omega^3 P_1 - \omega^3 P_2$  of the arc spectrum of tim. The second separation  $2^2 P_1 - 2^2 P_2 = 886 \cdot 2$  and the second principal pair  $1^2 S - 2^2 P_{12}$ , with the aid of the relativity doublet laws, have led to the two following pairs in the spectrum of Sb III (which is under investigation by us). These pairs probably form the con-

pairs probably form the consecutive members of the second sharp series of the spectrum.

λ.	Int.	ν.	$\triangle \nu_*$
4591·89 4265·089	(5) (6)	21771.5 $234396$	1668-1
4693·09 4352·25	(5) (6)	$\begin{array}{c} 21302\ 0 \\ 22970\ 2 \end{array}$	1668-2

In general features the first spark spectrum of tin is found to resemble closely the spectrum of Si II, analysed by Fowler. Details of the analysis will be published shortly.

Vizianagram, May 29.

### The Leeds Meeting of the British Association.

LOCAL ARRANGEMENTS.

AFTER an interval of thirty-seven years the British Association is again meeting at Leeds The City and University joined in a cordial invitation to the Association, and are working hard to live up to Yorkshire traditions of hospitality in connexion with the meeting The president, Sir Arthur Keith, has already made himself known to many citizens of Leeds when he addressed the Luncheon Club earlier in this year upon the subject of science and civilisation. His visit was much appreciated and increased the interest of many citizens in the coming visit of the great scientific Association over which he will preside

As in 1890, the Reception Rooms are in the Town Hall, which is centrally placed for all the stations upon the main railway lines serving Leeds. A special room will be put aside in the Town Hall for the convenience of members wishing to obtain information or tickets for the various excursions The ample accommodation available permits of the usual facilities for writing-rooms, refreshments, post office, etc. As usual, the Meteorological Office will have an exhibit, whilst a new feature will be a room put aside for the purpose of demonstrations by the British Broadcasting Corporation. In the crypt of the Town Hall an exhibition of scientific apparatus is being arranged, to which a number of well-known apparatus firms are contributing The general officers will occupy rooms in the City Education Offices, which face the Town Hall across Calverley Street. Meetings of the general committee and council will probably also be held in the Education Offices.

The secretariat will be at the Metropole Hotel, which is within two minutes of the Town Hall and of the Majestic Cinema, a fine building recently erected in the city, in which the presidential address will be delivered. The Majestic fronts upon City Square, in which Priestley's statue will be found, as also the Unitarian chapel of which he was at one time minister. The University is distant a short ride by tram along the Headingley route from City Square. All the meeting-rooms of the sections will be found either along this route or at the University. The meeting-rooms of the sections fall naturally into two groups: at the University will be found Sections A (Mathematical and Physical Sciences), B (Chemistry), C (Geology), D (Zoology), K (Forestry Sub-section), and M (Agriculture), whilst K (Botany) and G (Engineering) are in the immediate neighbourhood in the Trinity Congregational and Emmanuel Church School-rooms. Many of these sections will also have rooms in various University buildings for scientific exhibits, whilst luncheon and tea can be obtained at the University Refectory, at the Staff House and De Grey Road, or in the large Physics Laboratory. In the Engineering Lecture Theatre at the University several meetings are also to be held for the discussion of scientific problems connected with the textile industries. Of the other sections, I (Physiology) naturally finds

its home at the Medical School, whilst H (Anthropology) is appropriately housed in the Philosophical Hall, the headquarters of the long-established Leeds Philosophical and Literary Society.

These sections, as also E (Geography) in the Alexandra Hall, F (Economics) in the Y.W.C.A., J (Psychology) in the Masonic Hall, and L (Education) in the Albert Hall, are all close to the Reception Rooms and will amply be catered for, as regards lunch and tea, by the Reception Room and many restaurants in the shopping and Hotel quarters of the City in the immediate neighbourhood.

Many of the visitors will be staying in University hostels, or hostels of the Training College at Beckett's Park. Some of the University hostels are close to the University, and visitors staying at Lyddon Hall, College Hall, or University Hall will be able to lunch in hostel if they desire

The president himself will be the guest of the City in the Judge's Lodgings, which are conveniently situated with regard to the meeting-places of the Association, all of which are within a very short

distance of one another.

Leeds makes an excellent centre for those who wish to make themselves acquainted with the beauty spots of Yorkshire, and in consequence the local committee has arranged a wide field of excursions that should meet all needs. important abbeys in Yorkshire are to be visited under the leadership of well-known archæologists. Mr. Peers, of H.M Office of Works, will act as the leader of the excursion to Rievaulx and Byland Abbeys, while Prof. Hamilton Thompson will act in a similar capacity to the excursion to Bolton Abbey and Skipton Castle. The limestone country around Ingleborough is also to be visited, and opportunities for drives into Nidderdale and Wensleydale will be given. A local committee has been formed at York and Harrogate, and visitors to either of these places are assured of a hearty and interesting welcome. Probably a unique excursion is that to Gaping Ghyll where, thanks to the kind offices of the Yorkshire Ramblers' Club, a limited number of members will make the descent. In addition there will be a number of visits to works and factories in, and near, Leeds, and two visits to the Mines Rescue Station at Wakefield are included in the programme.

The Lord Mayor and Lady Mayoress are to give a reception to all members of the British Association in the Art Gallery on Thursday, Sept. 1, at 8 P.M., and on Tuesday evening, Sept. 6, the University of Leeds will entertain members at the University, when most of the scientific and technological

departments will be exhibiting.

Garden parties are to be given by Major Fawkes, of Farnley Hall, on Friday, Sept. 2—an exceptional opportunity for members to inspect the fine collection of Turner pictures that he possesses—and by Col. C. H. Tetley of Foxhill, the Pro-Chancellor of the University. On Saturday, Sept. 3, Lady

Lawson Tancred will entertain at tea those members who take the excursion to Aldborough. who are interested in textiles are invited by the British Research Association for the Woollen and Worsted Industries to visit its laboratories at Torridon on Thursday, Sept 1

Through the courtesy of the Leeds Choral Union a concert will be given in the Town Hall on Sunday, Sept. 4, at 8.15 P.M., and the items on the programme include Grieg's "Concerto," Elgar's The Dream of Gerontius," and Parry's "Blest Pair of Sirens "

On Tuesday morning, Sept 6, at 12 noon, a Congregation of the University will be held in the Great Hall, at which a number of honorary degrees will be conferred.

### Science and Industry in Italy.

THE opening on May 28, by the King of Italy, of the Volta Centenary Exhibition at Como is a reminder to the world of the progress of

Fig. 1.—Copy of bust of Volta by Gio. Battista Comolli.

science and industry in Italy. The land of great poets and painters, of famous churches and uni-

versities, Italy was one of the first countries to witness the rebirth of scientific studies, and from the days of Leonardo da Vinci the lamp of science has been kept burning. Just as the labours of Galileo and Torricelli, of Boscovitch, Vesalius, and Malpighi, of Avogadro, Cannizzaro, Secchi, and Schiaparelli have added lustre to her schools, so has the work of a long line of eminent hydraulic engineers engaged in harnessing the rivers of the Alps and Apennines made Italy famous as a nation of constructors.

Inaugurated to commemorate the centenary of the death of Volta, who passed away at Como on

its patrons Signor Benito Mussolini and Senatore Gughelmo Marconi. The site of the Exhibition is the spacious eighteenth-century mansion, Villa Olma, once the property of a great Milanese nobleman but now owned by the Commune of Como. It is in the fine ballroom of the villa, with its two-storied balconies, that many of the congresses will be held. In the villa itself is also displayed the collection of instruments illustrating Volta's own apparatus and his important in-

In 1899 another exhibition was held to celebrate the centenary of the discovery of the voltaic pile. but, as recorded in our columns at the time, on July 13 of that year practically the whole of the exhibition was destroyed by fire, and nearly all of the precious Volta relics perished—a loss to science only comparable with the destruction of Priestley's books, manuscripts, and apparatus in the Birmingham riots of 1791. Before the fire, however, photographs had been taken of the apparatus, and from these it has been possible to make replicas. The most interesting of these, perhaps, are the copies of the voltaic piles used by Volta in his demonstration in Paris when Napoleon attended a sitting of the National Institute, and the early forms of battery developed from the 'couronne des tasses.' As is generally known, Volta's invention of the pile was described in a letter written to Sir Joseph Banks on Mar. 20, 1800, from Como, and it was the information contained in the first part of the letter which led Carlisle and Nicholson to the experiment on the decomposition of water by the electric current.

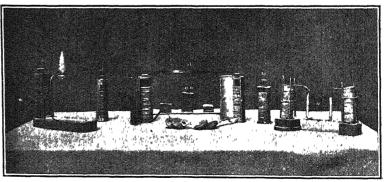

Fig. 2.—Examples of Volta's experimental piles

In the grounds of the Villa, temporary buildings have been erected, and in these and the house Mar. 5, 1827, the Centenary Exhibition has among | itself are displayed the various exhibits. The two most important sections of the exhibition are the International Exhibition of Electrical Communication and the National Electric Water Power Exhibition. To the former Senatore Marconi has lent a valuable collection of apparatus, some of which was used in his earliest experiments, together with a number of transmitting and

receiving instruments which were used in the days before the advent of the thermionic valve. Among the apparatus is a copy of that employed by Senatore Marconi in his experiments at his father's house at Bologna in 1895. No fewer than thirty-five states, including Great Britain, have sent exhibits, while the Italian Government have installed a short-wave radio station of 25 kw. power which will be working.

Of the work of the Italian nation in the extension of hydroelectric power generation and

transmission, much information is given by charts, photographs, etc., supplementing the review given by Prof. Emirico Vismara and others at the World Power Conference held at Wembley in 1924. Italy has taken a leading part in hydro-electric power development, and Prof Vismara recalled

rainfall, but with no coalfields, hydro-electric plants are a necessity to Italy, and these are now linked together so as to cover almost completely large portions of the country. It is an interesting economic feature, however, that with the development of electric power from water the importation of coal tends to increase and not decrease.

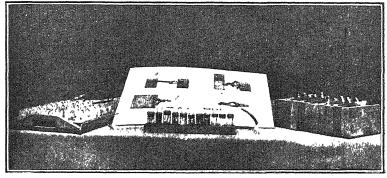

Fig 3 -Early voltage batteries and experiments on frogs' legs

During the course of the Exhibition, which will be open from May until October, many congresses will be held, amongst which the most important will be the Congress of Physics and the International Congress of Electrotechnics Distinguished scientific workers, many of them of international

repute, from Austria, Canada, Germany. Denmark, France, Great Britain, Holland, Italy, Russia, Spain, Sweden, Switzerland, and the United States, will attend the Congress of Physics. The universities of Great Britain will be represented by Dr F. Wil be represented by Dr F. W. Aston, Prof. W. L. Bragg, Prof. A. S. Eddington, Sir Ernest Rutherford, Sir J. J. Thomson, Dr. J A. Fleming, and Prof. O. W. Richardson, Canada by Prof. J C. McLennan; and India by Prof. M. Saka, At the same by Prof. M. Saha. At the conclusion of the Congresses the delegates will be conducted to Venice, Florence, and Rome, as the guests of the Italian Government, and the great national commemoration of Volta's centenary will take place at Rome in the Capitol on Sept. 19. The entire arrangements appear to have been planned on a scale

worthy of the occasion, and worthy of the place science should take in the daily life of every progressive nation. Centenary celebrations nowadays follow each other with increasing rapidity, but the Volta centenary commemoration is one which does homage to an outstanding figure in Italian science, whose discoveries have led directly to the applications of science by which Italy has become a great industrial nation.

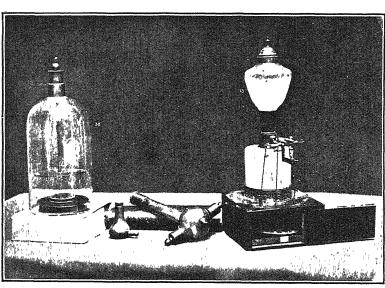

FIG. 4.—Volta's hydrogen lamp, electric pistol, and apparatus to test theory of hall formation

how, on the completion of the transmission line from Tivoli to Rome, 25 kilometers at 5000 volts, in July 1892, Kelvin, Ayrton, Preece, Crookes, Swan, Crompton, and others telegraphed: "The English Electricians send greetings to Electricians of Italy on completion of splendid enterprise of Tivoli, and wish them every success." Another notable achievement was the line from Paderno to Milan, carrying current at 13,000 volts. With her great mountain chains, with an abundant

# Excavations at Ur of the Chaldees, 1926-1927. By C. LEONARD WOOLLEY.

THE excavations started last year on Oct 28 and were closed down on Feb. 19 With the exception of Father Burrows, who replaced Dr Legrain as epigraphist, my staff was the same as in the former season, Mrs Keeling being responsible for the drawings, Mr Whitburn for the architectural side, and Mr. Mallowan acting as general archæological assistant; as foreman I had again Hamoudi from Jerablus, while his two sons were engaged, one as photographer, one as junior The number of workmen employed was smaller than usual, in view of the nature of our programme, and averaged about 130 The work fell into two distinct parts the excavation of building sites, principally the houses of the Larsa period, and the examination of a large prehistoric cemetery.

The house site lay just outside the sacred Temenos, against its south-west wall. Here we cleared parts of five streets, laying bare the remains, for the most part very well preserved, of fifteen houses, enough to give us a fair idea of town-planning in the period between 2100 and 1900 BC. Contrary to what excavations on other sites of later date had led us to expect, the houses proved to be remarkably well-built structures in burnt and crude brick, standing two storeys high, with an average for a moderate-sized house of twelve rooms. Of course the exigencies of ground space and of the owner's means introduced all sorts of variations, but throughout there was recognisable one general type. The house was built round a central courtyard on to which opened all the rooms, round this ran a wooden gallery reached by a staircase of brick below and of wood for the upper flight, giving access to the chambers of the top floor; the house roof extended over the gallery, sloping slightly inwards, and left in the centre a comparatively small opening which served as a light-well for the ground-floor: gutters round the edge of the opening led the rain water from the roof into a drain in the middle of the brick-paved court. It was possible to identify some of the rooms. The front door led into a small lobby communicating with the court, facing the entrance was the reception-room, on one side the kitchen, and below the stairs the lavatory, with a drain exactly like that of a modern Arab latrine. Altogether the arrangement and appearance of the house was precisely what one finds in the better quarters of Basra or Baghdad at the present day

We knew already that it was the custom to bury the dead under the floors of the rooms in which they had lived; this year we found an extension of the custom in that some of the houses were provided with a regular funerary chapel designed as part of the original building; the chapel was a long chamber having at one end a

 $^{\rm 1}$  From a discourse delivered at the Royal Institution on Friday, June 10.

the exa

brick altar and a column of brickwork (the meaning of this is uncertain), and below the pavement of the 'nave' there was a vaulted brick tomb which acted as a family vault, some containing as many as ten bodies interred at different times. In one case, instead of the tomb there were grouped round the altar clay bowls and coffins containing the bodies of infants, more than thirty in number; it would look as if the chapel were dedicated to some goddess who was a patroness of children.

One of the most important discoveries made in the houses was that of a fallen brick arch in one of the doorways This takes back the history of the arch as a feature of domestic architecture by several hundred years and enables us to work out reconstructions of buildings of this period (c 2100 BC) in a manner for which there was before no justification in fact. We can now be sure that the arch and the vault were regularly employed in temples, and it is not unreasonable to suppose, in view of certain peculiarities of ground-plan, that in the next great building period, that of 1400 B.C, the dome also was used. The chief 'finds' made in the houses were of inscribed tablets Many of these were ordinary business documents, but we have, besides a few religious texts, lists of the pious foundations of kings, grammatical texts and syllabaries, and mathematical tablets with such things as tables of square and cube roots, exercises in land mensuration, etc.

Work on building sites other than that of the Larsa houses threw much new light on the topography of the sacred Temenos, filling up what had been blanks on our general plan and leading to the identification of the great temple of the moon god Nannar in the time of Nebuchadnezzar; the discovery of a remarkable building set up by Sin-idinnam, king of Larsa (c. 2000 B.C.) about a mile to the east of the Temenos enclosure showed how widely scattered were the public buildings of the city and how much work remains to be done even after the excavation of the Temenos itself is complete. Further digging beneath the floors of the temple E-nun-makh, first excavated in 1922, brought to light new historical information and. amongst other objects, a set of ivory toilet instruments of fine Phœnician work and an ivory plaque bearing a remarkable Phænician inscription.

The second part of our season was spent in the examination of a cemetery lying at the southeast end of the Temenos and inside its later walls. The graves, distinguished by their levels and contents, belonged to three periods, the uppermost to 2800–2600 B.C., the next to about 3100 B.C., the earliest to some five hundred years before that. The upper levels were dated by inscribed cylinder seals, two graves of the first series belonging to members of the household of the daughter of king Sargon of Akkad, while from the second series came the seal of the wife of Mesannipadda, first King of the First Dynasty of Ur; the date of the

lowest graves was deduced from the very great amount of deposit separating them from the middle series and by the difference of script on the inscribed objects, this being semi-pictographic instead of fully developed cuneiform. In the lowest stratum the bodies are sometimes partly burnt, evidently a survival of an older practice of cremation, all signs of this disappear in the upper levels. The normal type of grave is a mere hole in the ground lined with matting in which the body was placed wrapped in a mat, the offerings were grouped about it and the whole covered with a second layer of matting before the earth was replaced Later, wickerwork coffins might take the place of the simple mats, and two or three wooden coffins were found. From the earliest times clay coffins were occasionally used, and these became more common as time went on, it is curious that the clay coffins, which would seem to be the more costly form of burial, were in fact the poorest in their furniture.

The objects from the graves were such as no previous excavations in Mesopotamia have produced, and it was noteworthy that in richness, in quality, and in technique they were better in proportion as they went back earlier in time. Though we have touched the oldest dateable strata yet found (I except that of the painted pottery, about which virtually nothing is known). it is clear that we have to deal with a civilisation which if not already decadent had at least been in existence for many centuries.

Most striking are the gold objects. The wealth of precious metal found in the graves is proof of the prosperity of the age, but also it is in these things that we have best evidence of its high state of culture, for the gold was the material on which the workman lavished most skill and it alone has suffered no decay. Not only beads, pendants, and personal ornaments are of gold, but we find even tools and weapons of gold or of electrum; these must have been ceremonial rather than for practical use, but they reproduce the forms of implements in copper and in silver Far the finest is a dagger of gold and lapis lazuli in a sheath elaborately decorated with filigree, besides this we have a spear-head, an adze, and two chisels of electrum. the handles of such weapons were of wood covered with gesso painted red and bound with thin gold Toilet utensils were made of the same metal—one set is in a finely decorated case—as well as in silver and copper; bowls, vases, and lamps were sometimes of silver, and one silver bowl is beautifully fluted and engraved

Engraving on shell was fairly common a set of plaques thus worked with animal subjects and framed in lapis lazuli and red stone was the most attractive, while a gaming-board with inlaid geometrical designs is perhaps of greater interest though of less artistic merit, a larger plaque showing a priest at sacrifice is an unusually fine example of the same technique. Ostrich eggs and sea-shells were sometimes encrusted with lapis, mother-of-pearl, and red paste. Stone vases in 'alabaster,' steatite, and limestone were very numerous, copper was astonishingly abundant, and we found one instrument of iron, this from a grave in the lowest stratum. The beads are of lapis and carnelian, very well cut and polished, and were set with others of silver and gold, the latter being often made with a thin plating over copper.

Only the pottery is disappointing in its quality. Sculpture is represented by some curious figures in unbaked clay and by a fragmentary but most important relief showing an empty chariot drawn by lions being led in procession, perhaps in the funeral procession of a king Lastly, we have recovered a great number of engraved cylinder seals invaluable for the study of early art forms. Altogether the season's work has produced a mass of material, much of it entirely novel, the importance of which for the early history of Mesopotamia it would be difficult to exaggerate I am glad to say that there is every reason to believe that discoveries of no less importance await us next winter.

### Obituary.

WE regret to announce the following deaths:

Mr. Charles Ford, I.S.O., Superintendent of the Botanical and Afforestation Department, Hong-kong, from 1871 until 1902, on July 14, aged eighty-three years.

Prof. Chas. W. Hargitt, research professor of zoology in Syracuse University and vice-president of Section F of the American Association in 1903, distinguished for his work on the coelenterates, on June 11, aged

seventy-five years.

Prof. A. Kossel, emeritus professor of physiology in the University of Heidelberg and editor of the Zeitschrift für physiologische Chemie, who was Nobel laureate for physiology in 1910, on July 6, aged

seventy-three years. Mr. John Macleod, I.S.O., formerly professor of mathematics at King's College, Nova Scotia, and the author of numerous original theorems in pure

geometry, aged eighty-six years. Mr. Hudson Maxim, inventor and manufacturer of explosives, of Brooklyn, New York, aged seventy-

Prof. M G. Mittag-Leffler, For Mem. R.S., formerly professor of pure mathematics in the University of Stockholm and founder and editor in chief of Acta

Mathematica, aged eighty-one years.

Mr. J. H. Reynolds, formerly Principal of the Municipal School of Technology (now the College of Technology), Manchester, and Director of Higher Education, who was president in 1913-14 of the Association of Technical Institutions, on July 17, aged eighty-five years.

Mr. B. Lewis Rice, C.I.E., formerly Director of Archæological Researches in Mysore and author of "Epigraphia Carnatica," on July 10, aged eighty-nine

Mr. G. B. Sudworth, for more than forty years dendrologist of the United States Forest Service and author of "Check List of Forest Trees of the United States, their Names and Ranges" (1898), on May 10, aged sixty-three years.

Mr. W. S. Valiant, curator of the Geological Museum at Rutgers College, known chiefly for his discovery of Ordovician trilobites in the Utica shales at Rome, New York, on Mar. 27, aged eighty-one years.

### News and Views.

THE Wild Birds Protection Bill is dead, after the second reading had given promise of a safe passage through the House of Commons. In the opinion of those best competent to judge, it was a measure designed to give better protection to British birds than even the old and scattered Acts, which it was to supersede, had done. But it has been killed by slogans devised by well-intentioned but less well-informed propagandists. It was called a "Rare Birds Protection Bill," yet it protected every bird in the country, it was sneered at because it gave different degrees of protection to different birds, but so long as some birds are persecuted and some are not, it is reasonable that the degree of protection should vary; it was said that the birds would be better off without the Bill. but the statement betrays lack of knowledge of the operation of the present Acts and the particular points on which experience has proved them to be weakest; it was said that public opinion was against the Bill, on the contrary, the informed public were in favour of the Bill. The death of the Bill is to be regretted by all interested in the effective protection of birds in Great Britain, the more so as its disappearance is due to the blind faith of certain members of Parliament in the propaganda of malcontents.

WICKEN FEN, under the care of the National Trust and its local committee, promises to become one of the most instructive of the natural reserves in Great Britain. It can never possess the grandeur of scenery or of fauna of the wild mountain areas of Scotland. but it has many advantages. It is unredeemed fenland, most of its 600 acres uncultivated and untouched. it contains a typical marsh flora with several rare ingredients and a rich insect fauna nourished upon the plants, and it is near a flourishing school of biology which has detailed experts for the analysis of the various plant and animal groups, with the result that a preliminary survey has almost been completed. It has been found, however, that the cost of keeping the reserve in order has outrun the funds devoted to the purpose, last year by a sum of £268, and the National Trust has launched an appeal for a capital sum of £10,000, the interest of which will be available for the upkeep of the sanctuary. It is also the intention to add 340 acres to the present reserve and "so put the whole property on a sound financial basis "

A NOTICE of the appeal for Wicken Fen which appeared in the *Times* of July 14 contained the statement that, left to itself, the fen flora would decrease by two-thirds of the present number, and that the fauna would shrink from 6000 species to fewer than 2000. In Nature's care, Wicken Fen would quickly become an impenetrable swamp, unmhabitable by many fen plants and animals. To retain the present balance, which represents a typical fen flora and fauna, considerable expense has to be incurred. If the sanctuary is to preserve these fen conditions, a limited amount of human interference is necessary, the cost of which is not met by present

resources A local committee of the National Trust, under Piof J Stanley Gardmer, is responsible for the area, and we are certain that money contributed towards the upkeep and extension of Wicken Fen sanctuary will be wisely spent for the furthering of knowledge of Nature.

THE British Medical Association has been celebrating the Lister centenary at its annual meeting during the past week-appropriately at Edinburgh this yearand, as part of the celebration, has issued a Lister memorial volume, which is one of the most complete that we have seen—"Joseph, Baron Lister" (Edinburgh and London: Oliver and Boyd, 1927. 10s. 6d. net). Apart from a biographical sketch of Lister's life, the work includes a number of reminiscences of 'The Chief' by surviving clerks, dressers, or house surgeons, amongst which is a contribution from the late Prof. Caird, the whole being edited by Dr. A. Logan Turner. An interesting section is that which gives a short account of the careers of Lister's fellowresidents at the Old Royal Infirmary, Edinburgh, in the summer of 1854, a group of men whose after history did not belie the promise of their early years. Two of Lister's addresses are reprinted, together with a number of obiter dicta from his published works. A chapter on the state of surgery before Lister's antiseptic work had banished the infections which too often followed surgical operations brings into full relief the great boon to mankind of his researches. His later surgical work perhaps rather overshadows his earlier physiological experiments, but the latter served as an excellent training and stood him in good stead when he came to devote himself entirely to the advancement of surgery. In virtue of the number of its contributors—upwards of a dozen—the volume gives an impression of completeness which may be lacking in one by a single hand. By perusal of these pages the reader may gain a very good idea of Lister's character and works, and of the development of the science and art of surgery at the period when he revolutionised its practice, the whole revealing a most fascinating story.

In a short note in NATURE of July 9, p. 59, dealing with some recent work in hydrodynamics, the opinion was expressed that during recent years the centre of gravity of pure hydrodynamical research appeared to have shifted to the Continent. The writer had in mind the new orientation given to this subject by the Prandtl theory and its various developments on the theoretical side, and the extraordinarily high degree of experimental skill exhibited in the production of the kinematographic films of fluid motion shown at Prof. Prandtl's recent lecture before the Royal Aeronautical Society. More mature consideration, however, suggests that the opinion so expressed was too sweeping, in that it did less than justice to the large body of British scientific workers who have contributed to this and other branches of hydrodynamical investigation. A wrong impression certamly tends to be created by the tardiness with which completed papers reach publication. Reports and Memoranda of the Aeronautical Research Committee, for example, are not usually available until anything from six to sixteen months after completion of the research. The result is that independent research workers not in direct touch with the personnel at Government research stations may remain for a considerable period in complete ignorance of important developments occurring in their own field.

A VIOLENT earthquake occurred in Palestine and Transpordan on July 11. According to the official report, 268 persons were killed and more than eight hundred were injured. The places that have suffered most are Maan (more than 60 miles to the south of the Dead Sea), Ludd, Ramleh, Nablus (Shechem), Amman, and Es Salt. Some lives were lost and historic buildings were damaged at Jerusalem and the villages round about, the Mount of Olives, Jericho, etc. So far as can be judged from the accounts already received, the centre of the area of destruction lies in the Jordan valley depression, near the southern end of the Dead Sea, the longer axis of the area being parallel to that depression. The last great earthquake in Palestine was that of Jan. 1, 1837. On this occasion the shock was strong enough to cause considerable damage at Beyrout, Damascus, Safad (where 3500 out of a population of 4000 lost their lives), Acre, Tiberias, and Jaffa. The epicentre was probably in the Jordan valley, not far from the Sea of Galilee, and therefore about 100 miles to the north of that of the recent shock. Of the two earthquakes, that of 1837 seems to have been the more violent. A rather strong after-shock was also felt on July 17 at Amman, Es Salt, Haifa, Jaffa, Jericho, and Jerusalem, with its epicentre thus about midway between those of the previous earth-

THE latest report of the Empire Cotton Growing Corporation (report of the administrative council submitted at the sixth annual general meeting on May 26) shows that the useful work which is being carried on by that body continues to expand and to produce good fruit, the production of cotton in the British Empire, excluding India, being 427,396 bales in 1925-26. The outstanding feature of the last twelve months was the fall in price in the latter half of 1926 from 10d. to a little more than 6d., a fall which has been a great discouragement to many growers, causing the abandonment of some areas. Already, however, the price from various causes has risen once more to 9d., and some of the defaulters are probably already regretting their hastiness. In general, though it may delay the hoped-for day when all or most of the cotton used in Lancashire shall be Empire-grown, this reaction will probably work for good by shaking out some of the weaker and more unprogressive cultivators, while at the same time allowing the specialist officers to press on with the breeding of the most valuable and useful types of cotton, and the Corporation and Governments con-

cerned to improve transport facilities before the pressure becomes too great.

THE work of the Empire Cotton Growing Corporation continues to expand, and the unexpended balance to diminish. The work in South Africa is first described, and though results have not yet been all that was hoped for, cotton appears to have come to stay as a crop that may ultimately cover large areas. In Rhodesia the beneficial results of rotation with mealies are becoming apparent—a step in the very desirable direction of regular rotation of crops with cotton, much useful work upon which subject has also been done by Mr. Sampson in Nyasaland, and is now being followed up by the School of Agriculture at Cambridge. Good work is being done in other parts of Africa in the breeding of improved varieties of cotton. The new Research Station in Trinidad is referred to, and the value of the work carried on there is expected to make itself apparent within a comparatively short period. An Imperial Agricultural Research Conference is to be held in October. Finally, the important work upon transport problems is referred to, and the subject of spinning tests is discussed. The whole report is well worth perusal.

UNDER the presidency of Prof. E. T. Whittaker an exceptionally interesting programme has been arranged in Section A (Mathematical and Physical Sciences) of the British Association for the Leeds meeting on Aug. 31-Sept. 7. The foreign guests include Profs. Millikan and Debye, and Drs. Heisenberg and Kolhorster. Prof. Millikan is speaking on the spectra of the elements of the first row of the Periodic Table, and is also giving an evening lecture to the Association on cosmic rays. Dr. Kolhorster will probably also speak on the latter subject in the sectional meeting. A paper by Dr. Heisenberg on recent progress in quantum mechanics will be followed by a discussion in which several English speakers will take part. Members will also have the opportunity of hearing Prof. Debye speak on the polar properties of molecules. Among other papers to be presented, those of Prof. Whiddington, Dr. Aston, and Prof. Barkla are of special interest at the present time. The joint discussion with Section B (Chemistry) on the structure and nature of colloidal particles will be opened by Sir William Bragg. There will also be several subsectional meetings. In mathematics a paper by Prof. Turnbull on non-commutative algebra will serve as a useful introduction to the discussion on quantum mechanics, and, in addition to papers by Profs. Milne and Brodetsky, a morning will be devoted to contributions on the theory of numbers.

In an article published in NATURE of August 28, 1926, Mr. F. J. W. Whipple, the Superintendent of Kew Observatory, made the suggestion that the study of the passage of sound through the high atmosphere might be promoted by systematic observations of the sound of gunfire. He was able to record that he had heard at Grantham seven discharges of a gun on the Shoeburyness range and had been able to

time the passage of the sound. This success has led to the organisation of an experiment which was tried last Saturday. At the request of the Meteorological Office, and with the sanction of the War Office, the times of discharge of a gun on the Shoeburyness range were broadcast by the British Broadcasting Corporation from Daventry and London. There were three rounds fired in the morning and seventeen in the afternoon. Observers were asked to listen for the arrival of the sounds coming through the air. The reports received at Kew Observatory indicate that no observers at great distances were fortunate enough to be able to hear the gun regularly, though there were instances in which likely noises were heard after one or two of the rounds Hot-wire microphones were in operation, however, at four places, and at one of these, the University of Birmingham, good records were obtained The time of passage of the air waves over a horizontal distance of some 130 miles was about 113 minutes. Birmingham must have been in the zone of 'abnormal audibility.' There are not enough observations to define the limit of the zone of normal audibility. The gun was heard intermittently at Romford, but not in the south of London. It is hoped that the broadcasting experiment will be repeated.

Among the activities of the Science Museum, South Kensington, is that of placing on exhibition collections of apparatus and specimens illustrating current scientific research. To some of these temporary exhibitions we have already directed attention. Thanks to the co-operation of the National Physical Laboratory, further collections were opened to the public on July 18 and will remain on exhibition for about four months. One of the new groups of exhibits relates to the research being carried out in connexion with the transport of apples, a matter of importance to the producer, carrier, and consumer. A great deal depends on the ventilation of the fruit stores, and here is shown the control device which automatically admits cool air into the store during the night and excludes warm air from entering during the day. Three exhibits deal with the metallurgy of dental alloys and amalgams, spectroscopic analysis, and British Standardised Steel Preparations. Amalgams are extensively used for dental fillings, but there is need for further knowledge of their properties. Unsatisfactory fitting often arises from the fact that the changes which occur during the mixing, setting, and hardening of the amalgams are only imperfectly understood. In this research microscopic study plays an important part. The exhibit by the Wireless Section of the Natural Physical Laboratory include short-wave transmitters with apparatus enabling wave-lengths to be measured within 1 mm.; a model short-wave receiver for use on wave-lengths of less than a hundred metres; typical examples of elaborate screening arrangements used in connexion with modern radio apparatus; a typical form of modern single frame-coil direction finder and photographs and diagrams illustrating the equipment used for the study of distortion in radio receivers.

A NOTE by Prof R. Verneau in the recent issue of L'Anthropologie (vol 37, Nos 1-2) directs attention to still another case of fraud in alleged archæological discoveries. In this case it is the neolithic mines with human figurines sculptured in chalk, engravings, decorated vases, stone axes, etc, which M. Lequeux claimed to have discovered at Spiennes, near Mons. An investigation carried out by La Service des Foulles des Musées in 1926 failed to find any of the galleries alleged to have been discovered, and the objects therefore remained without evidence of origin. M Verneau recalls a similar unauthenticated discovery of skeletons with bronze masks by M Lequeux in A commentary which needs no elaboration is afforded by the announcement that M Lequeux has just been arrested for violating graves in the cemetery of Montparnasse.

An article by Mr J D. Unwin on "Monogamy as a Condition of Social Energy" in the  $Hibbert\ Journal$ for July is interesting as an example of how anthropological data can be brought to bear upon the interpretation of history. It might even, perhaps, in an ideal State in which social organisation was an intellectual rather than an emotional process, serve to illustrate the practical value of studies at first sight rather remote from the conditions of modern life. Mr. Unwin has attacked the great problem of the historian —the rise and fall of great civilisations and empires. He shows that in the case of Sumeria and the early empires of Mesopotamia, Egypt and Crete so far as we have any knowledge, Greece, Rome, and the peoples of medieval and modern times, such as the Arabs and, up to a point, the British, this rise and tall in power presents a curve which agrees with the curve of progress towards the strictest form of monogamy and the departure therefrom in the relations of the sexes. Recent correspondence in the Tymes has suggested the responsibility of malaria for the decadence of Greece and Rome—a theory which was put forward by Mr W. H. S. Jones some twenty years ago or more. This suggestion is open to the objection that it offers one cause only for a very complex set of conditions, and Mr. Unwin's view would be obviously open to the same criticism did he suggest an immediate connexion. His conclusion is, however, far more subtle and by that so much the more plausible. He suggests that the 'force of life,' which primarily seeks satisfaction in sexual activity, is directed under a strictly enforced monogamy into other manifestations which lead to the advancement of the race or nationconquest, empire, art, and science.

In connexion with the celebration this month of the diamond jubilee of the Confederation of Canada, the Dominion Bureau of Statistics has compiled a handbook entitled "Sixty Years of Canadian Progress, 1867–1927," which is being distributed to libraries, schools, and other institutions. In about a hundred and fifty pages a survey is taken of most aspects of Canadian life, with particular reference to the natural resources and industries. Abundant statistics are given and there are many illustrations and maps, including maps of the growth of Canada, its climate

and forests An appendix gives the text of the British North America Act of 1867.

An expedition to the coast of Labrador for the study of its mollusca has lately left Washington under the auspices of the Smithsonian Institution. The members of the expedition complise Dr. Paul Bartsch, the Culator of Mollusks in the National Museum, and Mr and Mrs. Paul Bowman of the George Washington University. Its headquarters will be on the Matamek River on the south coast, where Mr. C. Amory has offered the use of his camp. The collection of anatomical material is to be the primary object, but special attention is to be paid to the environmental conditions in the places from which specimens are procured, while Mr. Bowman will study the flora and examine the peat bogs of the interior.

In accordance with the recommendation of the recent Colonial Office Conference, a Colonial Medical Research Committee has been appointed as follows: The Right Hon. W Ormsby-Gore (chairman), Sir George Maxwell (deputy chairman), The Secretary of the Medical Research Council (Sir Walter Fletcher), and the Chief Medical Adviser to the Secretary of State for the Colonies (Dr. A. T. Stanton), ex officio, Prof J W. W. Stephens, Sir Leonard Rogers, Dr. Andrew Balfour, Dr. Charles Todd, Dr. P. H. Manson-Bahr, and Dr. C. M. Wenvon. The terms of reference are. "To advise the Secretary of State and the Medical Research Council upon the initiation and promotion of medical research in the interests of the Colonial Empire, upon the recruitment and conditions of service of the necessary personnel, and upon the management and allocation of any funds available for these purposes" The Committee will also investigate proposals for the creation of a Colonial Medical Research Service, and for the payment from a pool of grants to medical institutions which are considered to deserve the support of Colonial Governments.

SPEAKING on July 18 in the House of Lords on the problem of river pollution in Great Britain, Lord Balfour stated that the Government has decided to set up a committee representing the Ministry of Health and the Fishery Board, under the chairmanship of Sir Holace Monro, to advise on the question of new legislation and administration. At the same time, scientific research on river pollution is being undertaken by the following committee: Sir Robert Robertson, Prof. V. H. Blackman, Prof. F. G. Donnan, Sir Alexander Houston, Mr. H. C. Whitehead, and Dr. G. C. Bourne; with Mr. Maurice, Mr Calderwood, Mr. Ronald, and Mr. Simpson-all connected with the Ministry of Health, the Scottish Board of Health, the Fishery Board for Scotland, or the Ministry of Agriculture and Fisheries—as assessors, and Dr. H. T. Calvert as director.

A NEW type of electric cord which acts as a push button at any point of its length is coming into use in Berlin in connexion with electric bells and buzzers and for starting and stopping machinery. It is the invention of Oscar Nagy, a Hungarian engineer. If the cable is squeezed at any point throughout its length, the circuit is completed and the signalling or operating device is actuated. This is effected by having the wires woven into a loose braid separated by an elastic non-conductor, which, however, makes contact when pressure is applied. It is expected that this device can be usefully employed with complicated machinery where threatened accidents to either operator or material make sudden stopping a necessity. It can be operated also by the knee or the elbow, and so has advantages over ordinary types of switches and push buttons. Hidden beneath carpets it would make a useful burglar alarm. In mines and quarries it could be arranged so that a fall or slide of rock would automatically sound an emergency signal

THE Hanbury Memorial Medal, which is given for excellence in the prosecution of promotion of original research in the chemistry or natural history of drugs, has been awarded to Dr T A. Henry, Director of the Wellcome Chemical Research Laboratories.

Dr. R King Brown, for many years Medical Officer of Health to the Borough of Bermondsey, where the practice of artificial light therapy has been extensively carried on under the Public Health Department, and chairman of the executive committee of the Institute of Hygiene, has been appointed medical editor of The British Journal of Actinotherapy.

The following have been elected to fill the vacancies which will occur in the council of the Institution of Electrical Engineers on Sept. 30 next: President: Mr. A. Page; Vice-President: Captain J. M. Donaldson, Hon Treasurer: Lieut-Colonel F. A. Cortez Leigh, Ordinary Members of Council: Mr. J. R. Beard, Major B. Binyon, Mr. P. V. Hunter, Mr. H. Marryat, Mr. H. T. Young, and Mr. D. N. Dunlop.

Some extra copies of the portrait of the late Arthur Bolles Lee, author of "The Microtomist's Vade-Mecum," which was issued with the last number of the Journal of Pathology and Bacteriology are available and may be had by any one interested on application to the editor at 17 Loom Lane, Radlett, Herts. It will be remembered that Mr. Lee died on Mar. 3 last.

The eightieth annual meeting of the Palæonto-graphical Society was held in the rooms of the Geological Society, Burlington House, on July 14, Mr. E. T. Newton, president, in the chair. The annual report referred to the completion of the monograph of the Upper Eocene flora of Hordle, and progress with the monographs of Gault Ammonites and Macrurous Crustacea. It also announced another instalment of the monograph of Palæozoic Asterozoa. Prof. Morley Davies, Dr. F. L. Kitchin, Mr. S. L. Wood, and Mr. Henry Woods were elected new members of council. Mr. E. T. Newton was re-elected president, and Mr. Robert S. Herries and Sir A. Smith Woodward were re-elected treasurer and secretary respectively.

Messes. Cooke, Troughton and Simms, Ltd., have issued a small catalogue (No. 553B) of portable survey

equipment which gives a wide choice of plane table outfits. The instruments cover equipment for purely graphic plane tabling as well as tacheometric instruments, as the pattern used by the Survey of India.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:-An analytical chemist at the Main Drainage Outfall Works of the Dublin Corporation—The Secretary, Local Appointments Commission, 33 St. Stephen's Green, Dublin (July 30). A junior engineer at the Forest Products Research Laboratory, Princes Risborough-The Secretary, Department of Scientific and Industrial Research, 16 Old Queen Street, S.W.1 (Aug. 4). A temporary botanist at the Royal Botanic Gardens, Kew-The Secretary, Ministry of Agriculture and Fisheries, 10 Whitehall Place, S.W.1 (Aug. 4) An assistant lecturer in the mathematics department of the Coventry Technical College-The Director of Education, Council House, Coventry (Aug. 5). A lecturer in physics, and assistant lecturers in mathematics, book-keeping, geography, and French at the Belfast Municipal College of Technology-The Principal, Municipal College of Technology, Belfast (Aug 5). An assistant lecturer and demonstrator in botany at the University College of South Wales and Monmouthshire—The Registrar, University College, Cardiff (Aug. 6). A male assistant in the geological depart-

ment of the Liverpool Free Public Museums, Liver-Appointments as follow, at the pool (Aug 30) International Institute of Agriculture, Rome -A chief of section specially qualified in tropical agriculture, and editors for, respectively, tropical agriculture, dairy science, plant diseases, fural economics, and trade in agricultural products—The Bureau du Personnel, Institut International d'Agriculture, Villa Borghese, Rome (Aug. 31). A woman B Sc. (physiology or biochemistry) at the Wellcome Physiological Research Laboratories - The Director, Wellcome Physiological Research Laboratories, Beckenham. Two junior assistants under the Directorate of Ballistics Research of the Research Department, Woolwich-The Chief Superintendent, Research Department, Woolwich, S.E 18. An assistant entomologist at the Wellcome Tropical Research Laboratories, Khartoum —The Controller, Sudan Government London Office, Wellington House, Buckingham Gate, S.W.1. A principal of the Leicester College of Technology-The Director of Education, Leicester. A lecturer in fuel technology at the Imperial College of Science and Technology-The Registrar, Imperial College of Science and Technology, South Kensington, S.W 1.

ERRATUM —In NATURE of July 2, p. 4, col 2, the second term of the left-hand side of the equation should read "2OH,"

### Our Astronomical Column.

COSMIC DUST CLOUDS.—The question of the absorption of light in space by clouds of cosmic dust is a very difficult one, and different observational results seem to lead to inconsistent conclusions. Prof. Shapley's study of the variables in the globular clusters indicates that the phases occur appreciably simultaneously in light of all wave-lengths; further, he finds that the clusters contain stars just as blue as any in our neighbourhood. These and similar facts tend strongly against any general absorption of appreciable amount. On the other hand, the occurrence of numerous regions with sharply defined boundaries, where there is a sudden drop in the stardensity (the Coal Sacks are a notable example), gives cogent reason to believe in the existence of local dust clouds which absorb nearly all the light from stars behind them.

Prof. Edward S King, of Harvard College Observatory, makes the suggestion in a recently issued Bulletin from Science Service, that the group of stars to which the sun belongs, extending outwards to a distance of a hundred light-years, contains a sensible amount of scattered dust. He bases this on observational evidence of increasing redness with distance up to the distance mentioned: after that he finds no further increase in redness. He notes the evidence of a large amount of scattered dust in the Pleiades as being a parallel case. It is well known that the Pleiades nebulæ give spectra similar to those of the stars that they surround, indicating that they shine by reflected light So Prof. King's result implies that the sun is a member of a local cluster somewhat similar to the Pleiades. His evidence for increasing redness with distance up to a hundred lightyears will be awaited with interest.

Shapley's result, mentioned above, shows that the time of passage of light through this cloud does not differ by more than a minute for light of different

colours. This gives evidence of the extreme tenuity of the supposed cloud.

Solar Radiation.—In Smithsonian Miscellaneous Collections, vol. 80, No 2, under the title "A Group of Solar Changes," Dr. Abbot continues his tests of the sun's intrinsic variability, as reflected in the measures of solar radiation made with the pyrheliometer at Montezuma. One test applied is to compare, for any given month throughout the interval considered, the averages of selected pyrholometer measures of total solar radiation with those of the solar constant This selection aims at comparing determinations. measures which have been made under as nearly as possible identical conditions, namely, when the sun is equally high above the horizon, the atmosphere equally clear, the quantity of atmospheric water vapour identical. For the observations discussed, 1921-1926, there is a very good agreement shown for each of the twelve months separately between the pyrheliometer and solar constant curves. On comparing either of these set of curves with that showing the sunspot variation for the corresponding periods, it is seen that a general similarity exists, but it is not so close for all months as was previously found for July, 1910-1920 (see Monthly Weather Review, May 1926).

A useful table is given of monthly averages of solar constant values determined at Chilean stations from 1918 to 1926. Dr. Abbot directs attention to indications in these figures of a 26-monthly period in solar radiation. As additional evidence of related solar and terrestrial changes, monthly solar constant values are compared with (1) ultra-violet radiation values, taken at Mt. Wilson; (2) long-range radio-signal intensities. During the interval, 1924–1926, for which comparisons are available, there is a marked accord. Dr. Abbot is sanguine that his continued investigations of solar radiation will yield useful positive results.

### Research Items.

Man's Origin —Still another view on the place and manner of the origin of man is put forward by Dr E A Hooton in Antiquity for June. Like other recent writers on this subject, he reviews our present knowledge of the geological, palæontological, and archæological evidence in each of the continents. In both Australia and America the probabilities are in favour of the late appearance of man, and the same is the case in South Africa, while the number of finds of the remains of early types of man in Europe lends great weight to the view that man may have originated on this continent. Dr Hooton is not inclined to accept the view recently put forward in favour of Asia, that in that area the modification of environmental conditions was responsible for a progressive modification of the stock, each receding from a common centre with the conditions to which it was adapted. On his view, the variations in man and his immediate precursors originated from generalised forms living in the Lower and Middle Miocene, and were due to the relinquishing of the arboreal habit at various times and at various points in a forest area stretching from the oriental region along the Mediterranean zone to western Europe and in Africa south to the farthest forest zone.

NORTH AMERICAN DIATOMS.—Mr. Charles S Boyer, NORTH AMERICAN DIATOMS.—AIR. CHARLES 5 Doyer, in his "Synopsis of the North American Diatomacee" (Part I. Cosemodiscatæ, Rhizosolenatæ, Biddulphiatæ. Proceedings of the Academy of Natural Sciences of Philadelphia, vol. 78, 1926, Supplement), states that "it is intended to comprise all recent species occurring in North America, including the West Indian" and bosins with a short introduction. West Indies," and begins with a short introduction and survey of the group, the volume in hand including the Centricæ and part of the Pennatæ. Whilst this is a valuable addition to diatom literature, it is by no means complete with regard to the planktonic On p 3, under Habitat, we find the following instructions as to the occurrence of marine diatoms, these are "obtained from dredgings, the scrapings of vessels or pilmgs, the stomachs of fish, the cleanings ot shells, and particularly from the surfaces of salt marshes and tidal pools." No mention is made of tow-nets and water bottles, and apparently the work of the many recent plankton workers, notably Bigelow of the Bureau of Fisheries since 1912 (published 1914 and up to the present tune), has not been consulted at all A beginner studying Mr Boyer's work would conclude that planktonic diatoms only occur plentifully in the open sea, whereas in reality they abound in coastal waters also. One has only to examine the records, for example, from Chesapeake Bay and the Gulf of Maine to verify this. To mention only a few important species which are omitted, we have Asterionella japonica, which occurred in profusion in the Gulf of Maine in 1914 (Bigelow), Guinardia flaccida, Chætoceros densum, Lauderia glacialis, and several others. Skeletonema costatum, that common neritic species, is merely said to be pelagic, and no mention is made of its pro-nounced preference for inshore waters. There is no index and no bibliography, very decided drawbacks in a work which is essentially one of reference, and it is to be hoped that they will be given in a future volume.

Burmese Helminthes—Prof F. J. Meggitt (Journal Burma Research Soc. vol. 15, part 3, 1926) records the results of examination of forty fowls from Rangoon, none of which was free from infection with tapeworms. The number of tapeworms present

varied from ten to several thousands. A species of Raillietina is much the commonest tapeworm in Burmese fowls, but a Hymenolepis is nearly as common while Amæbotænia sphenoides is comparatively rare. In England the common tapeworms of fowls are A. sphenoides and Davainea proglottina, while Raillietina was recorded only twice out of some 200 birds dissected. A key to the adult cestodes of towls is appended. In the same part, G. D. Bhalerao describes the intestinal parasites of bats in Rangoon and gives a list of the Trematoda recorded from Burma.

Canadian Copepods —Prof A. Willey in a description of a new species of freshwater copepod of the genus Moraria from Canada (Proc. U.S. Nat. Mus vol. 71, art 1, 1927) makes some observations on the distribution of copepods Giesbrecht (in 1892) directed attention to the fact that the calanoid fauna of the warmer parts of the ocean exhibits a greater degree of specific divergence than m the North Atlantic Prof. Willey remarks that the reverse is true of freshwater copepods, especially the harpacticoids, in which the number of species increases from south to north, a fact which not only suggests a northern origin for these forms but also points to their Pleistocene derivation. In other words, the northern freshwater harpacticoids as an ecologic group are relict forms of the post-glacial fauna. There is a further point that requires repeated confirmation—it was tentatively assumed by Piof Willey that North American freshwater harpacticoids differ to the extent of certain unit characters from their nearest representatives in the Old World, and he remarks that the present species seems to bear out that interpretation.

NUCLEAR DEGENERATION.—The March issue of Journal of the Royal Microscopical Society, which appears in a new form with larger pages, contains the presidential address by Dr. J. A. Murray on nuclear degenerations following multipolar mitotic cell-division. The material on which the studies described in the address were based was provided by the eggs of the sea-urchin fertilised by two sperms instead of by one. Boven showed that in such cases a tri- or quadri-polar mitotic figure results and the egg divides simultaneously into three or four primary blastomeres, after which cleavage proceeds normally by bipolar mitosis until the blastula stage is reached. But whereas in normal fertilisation each cell of the resulting larva receives a complete set of chromosomes from each parent, in disperm fertilisation the bipartition of each chromosome of the three sets of chromosomes (one from the egg and one from each sperm nucleus) between three or four asters, and consequently between the three or four primary blastomeres, inevitably entails a fortuitous distribution of the daughter chromosomes, so that each cell does not necessarily receive even one complete set of chromosomes. The varying abnormality of the descendants of the primary blastomeres is a consequence of this faulty chromatin distribution. Dr. Murray describes the nuclei of some of the descendant cells in which the chromatin is condensed into a homogeneous, hollow hemisphere in the concavity of which lies a highly refractile achromatic sphere. These cells form a striking feature of larvæ resulting from disperm eggs. In other pathological material, especially in higher animals, there is also the possibility that multipolar cell division, with consequent

derangement of the chromosome groupings, may have taken place, and, as Dr Muiray points out, it is perhaps not without significance that the most frequent sources of nuclear degenerations of this type have been met with in hypertrophic and hyperplastic conditions of the lymphatic glands. Dr Murray gives a group of figures illustrating nuclear degenerations, all taken from lymphomatous tumours of mice, in which the similarity of the appearances to those seen in the pathological echinoderm material is evident, and emphasises the need for attention to forms of cell degeneration in the analysis of pathological processes.

OXYGEN IN THE SOIL —Before the meeting in Washington of the First International Congress of Soil Sciences, Dr Lee M. Hutchins, of the United States Department of Agriculture, demonstrated the operation of an apparatus which he has devised to measure the oxygen-supplying power of the soil The essential part of the apparatus is a hollow vessel of porous porcelain buried in the soil to be studied Pure nitrogen is passed through it and the outgoing stream of gas is bubbled through a solution that changes colour if any oxygen is present. The shade of colour after a given time indicates the amount of oxygen that has passed from the soil through the walls of the vessel and into the nitrogen. Dr Hutchins has been using his invention to study the oxygen needs of such crops as corn and wheat, and also such plants as rice and willow, which can grow in soils that are water-logged and hence very poor in oxygen.

REST PERIOD AND GERMINATION.—Many devices have been used with varying success by plant physiologists to shorten the rest period which seems a necessary precursor to the germination of many seeds In the Malayan Agricultural Journal (vol. 15, No. 3, March 1927) J N Milsum describes some experiments to hasten the germination of oil palm seeds by means of the heat induced by growing seeds under glass. The temperature under the glass frames was 6° F.-18° F higher than the temperature of the open beds. One thousand seeds were planted under glass, and another 1000 planted under normal conditions as a control. After eight weeks, 523 of the heated seeds had germinated to 132 of the control set. After this period the percentage germination in the control beds rapidly approximated to that of the heated frames, so that after twenty weeks the ratio became 928 in frames to 857 in controls. The result of the experiments seems to be that under the given conditions, germination under glass accelerates germination by approximately five weeks.

THE TIDE AT TAHATI.—Under this title, H. A. Marmer publishes in the Journal of the Washington Academy of Sciences, vol. 17, pp 157-184, the results of harmonic analysis of observations extending over Particular interest attaches to tide at Tahati, since this island was considered to furnish a striking exception to the general rule that the tide follows the moon, for it was considered that high tide occurred every day at noon and midnight instead of coming later each day by about 50 minutes. Owing to the small range, amounting to barely one foot at springs, local conditions of barometric pressure and wind made the neap tides difficult to determine. The observations of the U.S. Coast and Geodetic Survey show that there is some progression of the times of high and low water from day to day. This progression is considerably less than 50 minutes about the time of spring tides, and considerably more about the time of neap tides.

Inflammability of Coal Dusts—The degree of fineness of a coal dust mainly determines the ease with which it can be ignited and can propagate flame when raised as a cloud in air. The fineness of a dust is not, however, the only factor on which the inflammability depends, but its chemical properties, which render it of greater or less reactivity towards oxygen, must also be taken into consideration. Paper No. 33 of the Safety in Mines Research Board (London: H.M. Stationery Office, 1927. 6d. net) describes experiments directed towards determining the effect, apart from any other factor, that the chemical composition of a coal dust has on its inflammability. The results disclose a relationship between the inflammability of a dust and its content of 'volatile matter' as determined by standard methods, the more inflammable dusts containing the higher proportions of volatile matter.

THE REFRACTIVE INDEX OF WATER.—An ingenious method for finding the refractive index of a liquid for short continuous electric waves has been described by L. E McCarty and L. T. Jones in the June issue of the Physical Review. A valve oscillator is suspended so as to affect two tuned receiving circuits simultaneously: one is separated from the transmitter by air, and a water trough is interposed in the alternative The two induced electromotive forces are employed to deflect the electron beam in an oscillograph, and the changes which take place in the Lissajou pattern as the thickness of liquid is varied give a measure of the retardation due to the latter, and so permit of calculation of its refractive index. The many experimental difficulties have still to be completely overcome, but it has been found that the refractive index of water is approximately constant and has a value of about 9 for waves of 3 m.-7 m. in length The authors hope to make an elaborate scries of measurements of dielectric constant and of refractive index under conditions as nearly identical as possible.

Subsoil Influences on the Inclination of Radio WAVE -J. E. Carrs, of the Watheroo Magnetic Observatory of the Carnegie Institution of Washington, has recently investigated experimentally the influence of a low resistivity layer subsoil on the forward inclination of radio waves. His conclusions are published in the Journal of the Washington Academy of Sciences, vol. 17, p. 264 It had been suggested that ground water, which is equivalent to a low resistivity layer, would almost entirely annul the forward inclination experienced by radio waves when travelling over ground of considerable resistivity, provided that the depth of the water was only a fraction of a wave-length below the ground surface The survey of the country round Watheroo Observatory showed that the surface layer, down to depths varying from 5 to 10 metres of the sand plain which comprises the greater part of the surrounding country, is of very high mean resistivity. At depths of 60 metres, however, its resistivity is only about one thousandth of what it is near the surface. The country, therefore, was admirably adapted for testing the theory. The Observatory was 132 miles north of the transmitter. The results prove that over soil consisting of a surface layer of sand of exceptionally high resistivity, which at a depth of from 60 to 100 metres had very low resistivity, radio waves of wavelength 1250 metres experienced no forward inclination As the resistivity measurements of the soil had been made with great precision, this gives a definite experimental proof of the effect of ground water, or a layer of low resistivity under the surface, on the polarity of radio waves.

### The Lister Institute.

THE thirty-third annual report was presented by the governing body at the annual general meeting of the Lister Institute of Preventive Medicine on May 18. In certain of the researches carried out by the Institute, the Medical Research Council, the Department for Scientific and Industrial Research, and the British Empire Cancer Campaign have cooperated by providing salaries or grants for the workers engaged: thus the Medical Research Council has provided the salaries of the staff of the National Collection of Type Cultures. On the occasion of the Lister centenary celebrations in April last, an address was presented from the governing body and staff by Sir James K Fowler, in the absence of the chairman, Sir David Bruce

Short abstracts of the scientific researches of the members of the Institute occupy the major part of the report, and are accompanied by a list of papers published during the year. A few only of these are selected for notice in the following account

In the department of bacteriology, Prof Ledingham has shown that the dermal reaction to vaccima virus can be prevented by injection of Indian ink into the cutis, either before or with the virus ably the ink stimulates the reticulo-endothelial system and increases the local defensive powers so that the virus fails in its attack on the tissues. A similar effect is obtained (in the rabbit) if the site of injection of the virus has been previously exposed to the X-ray or to infection by the streptococci of erysipelas. H Schutze and S S. Zilva have completed an investigation on the effect of diet upon the course of tuberculosis in animals guinea-pigs on a diet restricted in quantity were found to be less resistant to the progress of an infection than the In rats, sodium chaulmoograte was without influence on the lesions, but it appeared that a large excess of cod-liver oil or irradiation with ultra-violet light did inhibit their formation: the leucocytosis simultaneously produced is not the only agent in this inhibition, if concerned with it at all.

In the department of biochemistry, W. T. J Morgan has prepared the  $\alpha$ - and  $\beta$ -methyl hexosidediphosphoric acids from hexosediphosphoric acid, and is attempting to obtain the methyl hexoside from the former by means of Robison's bone enzyme. In collaboration with H. P. Marks he has shown that neither the mono- nor the di-phosphate will relieve the symptoms of hypoglycæmia in rabbits and mice following injections of insulin R. Robison has continued his work on the phosphoric esters occurring in blood, and has found that these compounds account for nearly all the acid soluble phosphorus present in this fluid: at the same time a compound which does not contain phosphorus but reduces alkaline copper solutions has been isolated and is being examined. He has also found that the bone enzyme will produce phosphoric esters synthetically, under suitable conditions, from inorganic phosphate and glycerol, glycol, mannitol, glucose, etc. In further experiments on calcification in vitro, the same author has shown that deposition of calcium phosphate in rachitic bones occurs when so little as 5 mgm. calcium and 5 mgm. morganic phosphorus per 100 c c. are present in the surrounding solution, provided that phosphoric ester is also present: so little as 0.5 mgm organic phosphorus per 100 c c has a significant effect, and the deposit increases proportionately to the increase in the ester

In the department of experimental pathology, the director of the Institute, Sir C. J. Martin, and Elizabeth Lepper have continued their investigations on the protein error of indicators in the case of horse-serum it was found that the serum-albumin diminished the colour of phenol red and neutral red, whilst the pseudoglobulin increased it Prof. Korenchevsky has found that after thyroidectomy, rabbits show a more pronounced fall of body temperature on cooling, and much less increase on warming, than normal animals. Castration has similar but less-marked effects, but para-thyroidectomy is without influence. Thyroid feeding will restore the power of adjustment to normal, but in excess will cause a marked rise of temperature under conditions previously well borne.

Work on vitamins includes assays of cod-liver oils carried out by the Institute on behalf of the Health Committee of the League of Nations: Miss Hume and Miss Henderson Smith have developed a new technique for vitamin A, in which the test material is fed to the experimental animals from the commencement of the experiment, the amount given to different animals mcreasing in geometrical proportion. For vitamin D assay, Miss Soames and Miss Leigh-Clare have worked out a basal diet containing both vitamin A and phosphorus in adequate amounts. They have also found that the vitamin D content of cod-liver oils is more uniform than the vitamin A content, and have obtained agreement between the biological method of assay of vitamin A and the colorimetric titration by the method of Drummond and Rosenheim. Miss Leigh-Clare has also been unable to detect any vitamin D in the marine diatom Nitzschia, so that this organism cannot be regarded as the ultimate source from which the cod obtains the antirachitic vitamin stored in its liver oil Miss Hume, Dr. Lucas, and Miss Henderson Smith have found that young rats and rabbits are protected from rickets when 0 2 gm irradiated cholesterol in hardened cotton seed oil is daily applied to an area of depilated skin equal to about one square inch, lending support to the idea that vitamin D may be synthesised in the skin when ultra-violet rays fall upon it. T. Lumsden in experimental researches on cancer has found that the immunity of an animal to an homologous tumour is the result of two factors: antibodies in the blood serum and some excretion from the white blood corpuscles when they have extravasated and are subject to a low oxygen tension.

In the department of protozoology, Dr Muriel Robertson has performed experiments on the parabasal body of the free-living flagellate Bodo caudatus: after treatment with acriflavine, a proportion of the organisms, otherwise appearing normal in their behaviour, were found to have lost the parabasal body, and in their progeny it is also absent. In studies on Heteromita it was found that, after nuclear division, the daughter cells sometimes failed to separate; the double individual which results from this non-separation gives a most realistic simulation of conjugation, so that it is not yet certain that the latter process occurs in this form.

In the department for the study and preparation of antitoxic sera, it has been found that with continued subcultivation in ordinary laboratory media the streptococcus tends to change its characteristics. Recent cultures are hæmolytic, virulent to mice, and appear 'rough' in broth medium, whereas the older cultures, into which the former tend to pass, are non-hæmolytic, less virulent, and 'smooth' in character. Their antigenic relationships are being investigated.

### The Spacing of Young Trees.

FOR some time past there has been a certain amount of dissatisfaction amongst a section of members of the Royal Scottish Arboricultural Society with the Transactions, it being held that the publication was behind the times, both in appearance, arrangement of material, and so forth. In the recently issued number for March 1927 the Council has taken the step of rechristening this conservative magazine as The Scottish Forestry Journal, though otherwise it remains unchanged Amongst the chief matters of interest in the present number is the attention given to spacing in planting in Great Britain, a point of vital importance The matter was given a prominent place in the presidential address of Sir Hugh Shaw Stewart to the Society last February (which is reproduced in this number), and was commented upon by partisans of both wide and close spacing during the ensuing discussion. It was touched upon by Lord Lovat in an address, also printed, and forms the theme of other writers.

It might appear, from some of the opinions expressed, that this question as to whether better results can be obtained by planting the young trees in the first instance at a closer or wider interval was a new problem. If it is new in Britain, it is merely due to the fact that when we commenced to plant conifers last century, we did so in ignorance of the methods in force on the Continent of Europe and knew nothing of that necessary concomitant—scientific thinning. The advocates of wide spacing, which, chiefly on account of the far heavier costs of planting since the War, is being practised both by the Forestry Commission and others, have, it must be confessed, few proofs to support their contention that they will obtain as good a quality of timber. That, in other words, they are not risking the reproduction of the inferior article which brought British timber into such disrepute that foreign conifer timbers were always preferred, if not demanded, even by the British Government Departments This question cannot be divorced from a consideration of the manner of growth of the larger area of the forests of the globe, which are of natural origin. In a naturally regenerated forest the young plants come up densely, and with proper attention are gradually thinned out. It would appear that those who advocate closer planting based on this analogy have a strong case.

The problem has to some extent become involved owing to the so-far-observed development of young plantations of Douglas fir. In many parts of Britain there has been an extraordinary variation in development of individuals in young Douglas woods in which the young trees were all of the same age and size when planted It may be agreed that the ordinary British planting distance of 4 ft. by 4 ft. or thereabouts, at first adopted for Douglas, was too close This is true, and, moreover, remains true for most exotic trees in any part of the world when introduced into a climate and under conditions which result in their growing very much faster in their early years than in their own habitats A forester going to the tropics has to revise all the ideas as to planting distances with which he became acquainted in temperate Europe. But because 7 ft or 8 ft. spacing may be correct for Douglas in Britain or parts of Britain, to apply the same spacing or anything near it to Scots pine, the spruces, and some other species is, in the opinion of many, to court disaster; or, at any rate, to reproduce an inferior British timber

Experiments are in existence in the form of sample plots and so forth, the object of which is to endeavour to provide rule-of-thumb information on this matter. But as we shall have to wait some thirty years or more ere results of any value are obtainable from them, it would conceivably be a wiser policy to imitate Nature as closely as possible, and not to hurry the planting campaign forward at the expense of the future quality of the marketable timber.

### Properties of Nickel- and Nickel-Chrome Steels.

EXTENSIVE researches on the nickel- and the nickel-chromium steels are described in a recent publication from the Bureau des Poids et Mesures <sup>1</sup> The memoir deals with work commenced in 1896 and continued consistently during the intervening years. Certain of the results have already been published in part from time to time, but the present collection serves a very useful purpose in bringing together in one volume work which has been spread over many years and published in very different places. Further, the results are now available in greater detail than has hitherto been the case.

Detailed descriptions are given of the apparatus and the methods used in the measurements, the majority of which, however, are by now fairly widely known. The properties chiefly investigated are magnetic—the Curie point, the dilatation and the torsional modulus of elasticity. The account of the work on the nickel steels by M. Guillaume deals in the main with changes in these properties over a relatively small temperature range, but M. Chevenard considers the changes in the nickel-chromium steels up to quite high temperatures.

One of the most interesting aspects of the work is the interpretation offered of the well-known but curious properties of 'invar' and the less generally

1 "Travaux et Mémoires du Bureau des Poids et Mesures." Publics sons les auspices du Comité International, par le Directeur du Bureau Pans, 1927. known, but equally interesting, constancy of the modulus of elasticity with temperature of the nickelchrome steel to which the name 'clinvar' has been given. In each case the presence of an intermetallic compound is invoked in order to explain the results, compounds which are not believed by all metallographers to have any real existence. Regarding the one which is believed by the authors to occur in 'invar,' it is stated that "this compound Fe<sub>2</sub>N<sub>1</sub> is formed with expansion, and its magnetic transfor-mation is accompanied by an anomalous negative dilatation and by an exceptionally large positive thermo-elastic anomaly. Its presence explains the appearance of the minimum in the curves of density and modulus of elasticity with composition at the ordinary temperature." The ferro-nickels which contain chromium show a reversible magnetic transformation just as do the pure iron-nickel alloys. The higher the content of chromium for the same amount of nickel, the lower is the Curie point and the less pronounced are the anomalies of dilatation and elasticity. This intense diluent effect of chromium appears to point to the presence of a compound Ni<sub>2</sub>Cr<sub>3</sub>, and one may obtain alloys either of a determined dilatability or of constant elastic properties as in 'elinvar.' The latter alloy, in addition to nickel and chromium, actually contains carbon, manganese, and tungsten.

So far as more directly important practical applica-

tions of these steels are concerned, M Chevenard says that "chromium exerts a very favourable influence upon the mechanical properties of the austemitic nickel steels, especially at high temperatures At the same time it renders these alloys very resistant to oxidation and to the attack of a large number of corrosive agents." These facts are already being applied industrially in the newer varieties of stainless iron and steel.

The volume ends with a paper on butt-ended standards of length which forms the continuation of

previous work

### The Supply of Information.

IN October 1924 the President of the Board of Education appointed a Departmental Committee to inquire into the adequacy of the library provision already made under the Public Libraries Acts, and the means of extending and completing such provision Those who recognise that an efficient library system is the essential foundation for progress in education and culture, without which no people can hold its own in the struggle for existence, will welcome the Report 1 of the Public Libraries Committee, a volume of some 350 pages now published, as offering the basis

for a reorganisation long overdue.

The Committee recommends a national system of co-operation between libraries, whether borough, urban district, county, or special, with the Central Library for students, reconstituted as a department of the British Museum, acting as a central bureau of exchange for the whole system, and as a national lending library to supplement the resources of other libraries. It is contemplated that, in the first place, an application for a rare or expensive book needed for the purposes of research will be made to the local public library. If the public library does not possess the book and does not consider it reasonable to buy it, the librarian will refer to the 'regional library, provided such an organisation has come into being. If the regional library cannot supply the book, the application will be sent to the Central Library. The Central Library will supply the book from its stock, endeavour to borrow the book from the institution likely to possess it, accepting responsibility, or purchase the book.

A considerable proportion of the books for which application will be made under this scheme will be scientific literature, and in particular scientific periodicals. The necessity for a central library to provide for the needs of scientific workers has been widely recognised and was emphasised by Dr. Chalmers Mitchell at a conference of the Association of Special Libraries and Information Bureaux in 1925, when he said: "Some of the periodicals are contained in no library in Great Britain. I am glad to be able to state that the Library of the Science Museum is making a great effort to fill the gap. In my view there is no more urgent need than the establishment in this country of a central library, the duty of which shall be to contain a copy of every periodical publish-

ing scientific research."

The nucleus of such a library already exists in the Science Library at South Kensington, with its great collection of periodicals. The Committee suggests that the most easy and least expensive way of solving the problem will be to make the Science Library complete, and it recommends that an additional sum of £3500 a year, with a small contingent increase of staff, should be granted to enable the Science Library

<sup>1</sup> Public Libraries Committee Report on Public Libraries in England and Wales, pp. 356. Cmd. 2868. (London H M. Stationery Office, 1927) 6s. net.

to obtain most of the volumes of which it stands in need. The Science Library has already assumed many of the functions of a central library, by the extension of borrowing facilities to approved institutions where scientific or technical work is carried on, and should be the principal source on which the Central Library will depend for the supply or loan of books needed by research students in science.

If scientific research is the foundation of commercial prosperity, it is no less true that such research cannot be carried out efficiently without the means of consulting the records of previous work The organisation necessary to secure this end would not be very great It is estimated that the cost of all the proposals, including those relating to the Central Library and the Science Library, would not exceed £12,000 a year during the next few years, while the benefit to learning, research, manufactures, and trade can scarcely be estimated.

### University and Educational Intelligence.

EDINBURGH —At the recent graduation ceremonial, the honorary degrees conterred included the following: Doctor of Divinity. The Right Rev. Ernest William Baines, Lord Bishop of Birmingham. Doctor of Laws Sir John Carruthers Beattie, Vice-Chancellor and Principal of the University of Capetown; the Abbé Henri Breul; Prof C. F. Jenkin, professor of engineering, University of Oxford; Prof. J C. Meakins, professor of medicine, M'Gill University, Montreal, Prof. A. C Seward, Master of Downing College and professor of botany, University of Cambridge. The degree of Doctor of Science was conferred on Douglas A. Allan, thesis—"The Geology of the Highland Border from Tayside to Noranside", T. W. M. Cameron, thesis—"Studies in Economic Helminthology". John Maggiere Cowen, thesis—"The thology"; John Macqueen Cowan, thesis—"The Forests of Kalimpong—An Ecological Account"; J F V Phillips, thesis—"Forest Succession and Ecology m the Knysna Region"; C. M Yonge, thesis—"Structure and Function of the Organs of Feeding and Digestion in the Septibranchs, Cuspidaria, and Poromya"

LONDON .- A course of four lectures on "Heat Transfer in Reciprocating Engines, including Internal Combustion Engines," will be given (in English) by Prot. Dr. Adolf Nagel, professor of engineering in the Technische Hochschule, Dresden, at the Institution of Civil Engineers (by kind permission) on Oct. 11, 14, 18, and 21, at 5 30 PM. The lectures will be illustrated by lantern slides Admission is free, without ticket.

The International Federation of University Women in its Occasional Paper, No 6, describes Crosby Hall, the Federation's new office which was recently opened by the Queen as a club-house. University women carrying on research or other post-graduate work in London will be eligible for residence at the Hall, if members of the Federation, and the dining-hall and common rooms are available for all members visiting or living in London. The same pamphlet contains addresses by Prof. Zimmern and Prof. Kristine Bonnevie on the work of the League of Nations Committee on Intellectual Co-operation and the Federation's collaboration with it, and a note on the functions of the American National Committee on Intellectual Co-operation, described by Prof. Zummern as the model national committee. American committee, organised at the beginning of last year, undertakes to procure or compile whatever information from the United States may be needed in connexion with any investigation being made by the International Institute of Intellectual Co-operation, the working instrument of the League of Nations Committee. It has been interesting itself in the question of obtaining financial support for the Geneva School of International Studies and for a working library for the Institute. The Federation has a committee on standards which is engaged in investigating the thorny problem of assessing the relative values of the degrees and diplomas granted by the various universities and other institutions of university standing.

THE Trustees of the Bert Fellowships for Scientific Research at their recent twelfth annual meeting elected the following to fellowships, the proposed course of research being indicated after the Fellow's name: Mr. I. Vogel, ring formation (Organic Chemistry Laboratories of the Imperial College, under Profs. H. B. Baker and J. F. Thorpe); Mr. K. V. Thunann, the effect of electrical currents on proteins (Bio-chemistry Department of the Imperial College, under Sir John Farmer and Prof. S. B. Schryver), Mr. A. G. Forsdyke, the nature of the motion in the wake of a body moving in a viscous fluid as a contribution towards the problems of fluid resistance (Mathematics Department of the Imperial College, under Profs. S. Chapman and H. Levy). All these fellowships are of the value of £250 a year and tenable at the Imperial College of Science and Technology. In addition, the Trustees approved the extension for a second year of the fellowships held by Mr. J. Topping for research on the mechanical equilibrium of crystal lattices, Mr. J. W. Maccoll for studies in the motion of viscous fluids, and Mr. G. H. Mitchell for further work on the geology of the Borrowdale volcame series of Kentmere, Westmorland The experiment during the past year, under which the tenure of these fellowships was tentatively made for two years instead of one year as before, having proved successful in every way, the Trustees have now adopted it as the tenure basis of the new fellowships now announced and of future awards.

The report on the work of the Department of Petroleum Technology of the Sir John Cass Technical Institute for the session 1926-1927 has recently been issued, and in it the Principal, Mr George Patchin, is able to show some satisfactory results of development. Since the last annual report (1925–26) the Department has been enlarged by the addition of a Petroleum Technology Laboratory with a fully equipped lecture room adjoining the same; it is hoped that this extension will provide the necessary facilities for advanced study and research The schedule of lectures given during the past session comprises lectures on petroleum technology (in three parts), introduction to the chemical and physical properties of petroleum, properties, applications, and examination of petroleum, and the applications of engineering and mechanical drawing. For those who have little or no previous knowledge of the fundamental sciences, there is a preliminary course, including elementary chemistry, physics, and practical mathematics. It is not clear from the report what subjects are comprised in the petroleum technology course, other than part 3 dealing with internal combustion engines and colloids in relation to petroleum. It is to be hoped that provision is here made for those who wish to acquire some knowledge of the geological aspects of the industry, also that the important subject of economics of petroleum is included. Close contact has been kept between the school and various oil companies in London; in this connexion lectures have been given by members of the staffs of the latter, and thus essential practical knowledge is placed at the disposal of the students, a vital factor in the training of all concerned with the petroleum industry, whatever particular branch is favoured.

### Calendar of Discovery and Invention.

July 24, 1747.—About the same time that Franklin was experimenting on lightning conductors, William Watson (1715–1787) made experiments which appeared to show that the passage of electricity was instantaneous. Some of these experiments were made in the summer of 1747. On July 24 of that year Watson, assisted by Charles Cavendish and Martin Folkes, sent a charge of electricity through 800 feet of water at the New River, Stoke Newington. The following year Watson, at Shooter's Hill, also sent discharges through 12,276 feet of wire.

July 24, 1842.—"That a glacter moves like a

July 24, 1842.—"That a glacier moves like a sluggish river, and under the same laws," wrote J D. Forbes, "was an idea which first clearly entered my mind as a definite probability on the evening of the 24th July 1842, when from the heights of the Charmoz I saw the dirt bands stretching across the breadth of the Mêr de Glace at my feet like floating seum on a partially stagnant stream . . . and from that hour the viscous or plastic theory was to me a conviction and a reality."

July 25, 1675.—Halley was the son of a wealthy soap boiler whose town house was in Winchester Street, in the city of London, and it was here that Halley, on July 25, 1675, observed an eclipse of the moon. He was then nineteen years of age and this eclipse formed the subject of his earliest published observations.

July 25, 1909.—The first flight in an aeroplane across the English Channel was made by Louis Blériot, who on July 25, 1909, crossed from Calais to Dover in a monoplane of 28 feet span, weighing with the pilot 462 pounds. The machine was fitted with a three-cylinder Anzani engine developing 24 horse-power.

July 26, 1790.—What was probably the earliest advertisement of a steamboat appeared in the Federal Gazette and Philadelphia Dauly Advertiser on July 26, 1790. This gave notice: "The Steamboat sets out to-increw at 10 o'clock from Arch Street Ferry, in order to take passengers from Burlington, Bristol, Bordentown, and Trenton, and return next day. Philadelphia, July 26, 1790" The steamboat referred to was one of those built by the unfortunate pioneer, John Fitch.

July 28, 1851.—In the development of the study of the various phenomena associated with total eclipses of the sun, especial interest is attached to the total eclipse of July 28, 1851, observed with success in Norway and Sweden. It was on this occasion that the prominences were closely followed and described. Hind wrote of "a long range of rose-coloured flames"; Dawes of "a low ridge of red prominences, resembling in outline the tops of a very irregular range of hills," while Airy termed the portion of this "ringged line of projections" visible to him the "Sierra."

July 29, 1857.—An outstanding improvement in the manufacture of iron rails was the introduction of the 'three high mill,' in place of the 'two high mill.' The story of its introduction was told by the great American ironmaster, John Fritz, in 1899. Declared by others "a visionary scheme and one that had never been done before, and had it been practical it would have been done long ago," the first 'three high mill' was put into action by Fritz himself at the Cambria Iron Company, U.S.A., making the company a great financial success and giving it a rail plant far in advance of any other plant in the world.

July 30, 1828.—An account of the Brownian movements witnessed by Robert Brown was privately circulated under this date, with an additional account the following year dated July 29, 1829. E. G. S.

### Societies and Academies.

#### LONDON.

Royal Society,  $^1$  June 30.—A. Fage and F C. Johansen. On the flow of air behind an inclined flat plate of infinite span. The airflow behind a flat plate has been explored with a heated wire, used in conjunction with an Einthoven galvanometer. As the inclination of the plate is decreased from 90°, both the frequency and velocity with which individual vortices behind the plate pass downstream become greater, and the longitudinal spacing between successive vortices becomes smaller. Vorticity is shed at the same rate from the two edges of the plate; this rate slowly decreases with the inclination of the plate Only a part of the vorticity generated at the edges passes downstream in the form of well-defined vortices

L. G. Brazier: On the flexure of thm cylindrical shells and other 'thm' sections St. Venant's solution of the flexure problem shows that hollow beams are more efficient than solid beams in economy of material. His theory suggests that this advantage increases without limit as the cylinder is made of thinner material. Actually a limit is reached when the section fails under flexure by distortion of the cross-section. The distortion of the cross-section of 'thin' section beams subjected to pure flexure is examined and a modification to St Venant's result is obtained. The analysis suggests the existence of a form of elastic instability, characterised by the absence of a 'point of bifurcation,' for beams of such sections subjected to pure flexure.

W. H. George and H. E. Beckett: The energy of the struck string (Part II.) The initial velocity of the hammer does not determine the character of the impact, and the fraction of its initial energy lost by the hammer is independent of the initial velocity of the hammer. The results obtained with an actual felt-covered pianoforte hammer are remarkably like those for a pointed or a broad unyielding metal hammer. A specially designed yielding metal hammer gave less energy to the string than did any of the other types of hammer. The partition of the energy among the various partial tones of the vibrating string shows that it would be possible to obtain almost any kind of tone quality from a pianoforte merely by altering the mass of the hammer.

G A. Tomlinson: Rusting of steel surfaces in contact. Hardened steel surfaces m contact and subject to relative motion are liable to become stained with a deposit of oxide, which may cause trouble in high-precision apparatus. This effect trouble in high-precision apparatus. occurs with quite small contact stresses and with various different materials in contact with steel. It is necessary that relative tangential motion shall occur. An oscillatory tangential motion of  $8\times10^{-8}$  inches, repeated sufficiently often, will produce oxidation débris, but smaller motions do not. This suggests that actual molecules are detached by cohesion forces and combine with oxygen molecules from the air. The effect of a film of castor oil between the surfaces has been examined. A sphere and a plane can be completely separated by a film of great mechanical strength, when the mean intensity of pressure over the area of contact is less than a critical value of about 65,000 lb. per square mch. For pressures above this, the film may rupture and solid cohesion occur, accompanied by the same oxidation

F. I. G. Rawlins and E. K. Rideal: The absorption spectra of aragonite and strontianite in the near infra-red. Definite displacements of the three

<sup>1</sup> Continued from p. 103

fundamental frequencies of the CO3-- ion occur in the two crystal forms From the overtones of the fundamental at  $7\mu$ , it is shown that the frequencies do not follow the order  $3\nu_1$ ,  $2\nu_1$ ,  $3\nu_1$ ; a correction must be introduced analogous to the Kratzer correction for an harmonic coupling in gases In CaCO3 this correction is greatest for the less symmetrical form. In bi-axial crystals of the carbonates of calcium, strontium, and barium, the absorption wave-length at  $\nu_1$  (7 $\mu$ ) and its overtones increase with the molecular volume, but the reverse is the case for the bands at  $\nu_2$  (14 $\mu$ ) and  $\nu_3$  (11 $\mu$ ). This dependence upon the molecular volumes is likewise observed in calcite and

C. N Hinshelwood and P. I. Askey. The influence of hydrogen on two homogeneous reactions. The decomposition of propionic aldehyde is unimolecular at low pressures if sufficient hydrogen is present Increasing pressure of hydrogen soon brings the propionic aldehyde reaction to a limiting rate, which is the same as the limiting rate reached when the partial pressure of the aldehyde itself is increased Similar pressures of hydrogen have no tendency to make the acetaldehyde decomposition appear unimolecular, and no saturation value is reached for the comparatively small effect which the hydrogen exerts. These phenomena indicate that activation of acetaldehyde involves a few degrees of freedom only, while that of propionic aldehyde is a more complex process, and that in the propionic aldehyde reaction there is a time-lag between activation and transformation.

H. Stanley Allen and Ian Sandeman: Bands in the secondary spectrum of hydrogen (11.) A system of bands of a distinctive type occurs in groups throughout a wide range of the visible and infra-red spectrum of hydrogen. The bands in a group have been spaced out at intervals of very nearly 92 wave-numbers, and various reasons have been given for attributing the system to triatomic hydrogen,  $H_3$ . A considerable number of new bands has now been added. The structure of some of the better defined bands suggests

that the spacing depends on a new quantum number. G. D Bengough, J. M. Stuart, and A. R. Lee. The theory of metallic corrosion in the light of quantitative measurements. A new version of the electrochemical theory of metallic corrosion has recently been widely accepted as fitting satisfactorily experimental facts, from a qualitative point of view, but the theory has not been subjected to exact quantitative examination. A method of measuring corrosion has been worked out, based on the determination of the amount of oxygen absorbed during corrosion, and has been applied to the metal zinc. The nature of the surface of the metal is an important factor in determining corrosion. Reasonable agreement between duplicate experiments has only been obtained with specimens annealed in argon at temperatures in the neighbourhood of 250° C. 'Spectroscopically' pure zinc is readily attacked by N/10,000 KCl solution; in solutions between N/20,000 and N/5000 KCl the time-corrosion curves are of exponential form during their earlier course, and the controlling factor appears to be the number of chlorine ions initially present in, and their rate of withdrawal from, solution. later course of the curves appears to be controlled largely by the behaviour of films of corrosion products. With stronger solutions the amount of available oxygen becomes an important factor.

H. A. Wilson: Chemical equilibrium in a mixture of paraffins. The compositions of the gaseous and liquid phases of a mixture of paraffins,  $C_nH_{2n+2}$ , when in a state of chemical equilibrium, are worked out approximately as functions of the temperature and pressure. A chart is drawn on which the equilibrium

composition of the phases can be read off. The results obtained enable the temperatures and pressures at which the maximum amount of any particular paraffin is present in the vapour to be determined. The amount of the gaseous phase which condenses when the temperature and pressure are changed can also be obtained.

Physical Society, June 10.—J. H. Awbery. The latent heat of evaporation of sulphur. The latent heat of evaporation of sulphur was determined by finding the loss of weight of a vessel full of sulphur when energy was dissipated in it at a known rate. Heat losses were prevented by immersing the vessel in the vapour of sulphur. The value found for the latent heat was 79, the accuracy being estimated at 2 per cent.—H Lowery. The refraction and dispersion of gaseous carbon tetrachloride. The refractive index has been found for the green mercury line ( $\lambda 5461$ ), the result being expressed in connexion with the density of the gas, that is, so as to show the refractivity of the gas by the same number of molecules as 1 c.c. of hydrogen contains at N.T.P. Adopting the value 1.001799 for the refractive index under these conditions, the dispersion of the gas over the range  $\lambda4800$  to  $\lambda6700$  is represented by the expression  $\mu-1=13~543\times 10^{27}/(7831~7\times 10^{27}-\nu^2),~\nu$  being the frequency of the light —P. K. Kichlu: Regularities in the spectrum of ionised neon. A number of lines lying between  $\lambda 7282$  and  $\lambda 3142$  occurs in the condensed discharge spectrum of the more volatile gases of the air. These have been attributed to singly ionised neon, and the present work confirms this

Royal Anthropological Institute, June 28.—V. G. Childe: The Ægean and the Danube valley in the second millenium B.C. The Central European bronze age was the child of the Ægean but eventually turned upon its parents and devoured them. Recent excavations in Hungary and Macedonia have thrown light on this double process In the lowest strata at Toszeg near Szolnok on the Tisza, the connexion with Troy is clearly revealed in the pottery, and at the same time a link is found with the early bronze age civilisation that arose round the tin deposits of Bohemia. In the fourth layer at Toszeg, an intrusive pottery appears that is identical with a foreign ware found by Mr. Heurtley in a sub-Mycenæan context in Macedonia This fabric was native neither to Macedonia nor to Hungary, but originated round the headwaters of the Adir and March. Its authors could be traced as far as Thessaly and central Greece. Were they the Dorians of Greek tradition?

### PARIS.

Academy of Sciences, June 13.—Marcel Brillouin. The earth's magnetic field and the internal electromagnetic properties of the globe.—J. Costantin: The economic and agricultural importance of cultivation in tropical mountain regions. An account of the fight against the sugar-cane disease (Sereh) in Java. The simplest treatment, and the one in general use, is to raise the cuttings of the plants in the mountains, first at an altitude of 1500 m. to 1800 m., then removal to nurseries at a height of 600 m. to 700 m., and finally removal to the plain. The regenerated plant remains free from disease for about five years. A modified treatment is to cross the Java cane with a mountain variety from the lower slopes of the Himalayas and to give this the mountain cure as above, about every six years.—Gabriel Bertrand and L. Silberstein: The amount of total sulphur in arable soil. Analyses of soil from various parts of

France showed the total sulphur to vary between wide limits-0.202 gm. to 5.175 gm. of sulphur per kilogram of dried soil. It was noticed that the regions nichest in sulphur were also the most fertile.—A. Desgrez and H. Bierry: The variations with the diet in the elimination of the urinary carbon in diabetics. Two ratios have been experimentally studied,  $A = (C_t - C_g)/N_t$ , where  $C_t$  is the total carbon in the where  $C_u$  is carbon as urea and  $N_u$  the nitrogen as urea. Both these ratios are at a minimum during the period of an equilibrium diet, and the measurements of these ratios establish with precision the value of a particular diet for diabetics.—Beniamino Segre The transformation of R networks.—A. Buhl: The symmetries of the theory of continued groups.— Léon Pomey · The normal integro-differential equations of infinite order.-V. A. Kostitzin: The singular solutions of the integral equations of Volterra—René Lagrange · an algorithm of series —M Lavrentieff · Conformal representation.—Spyridion Sarantopoulos · The meromorph functions represented by a Taylor's series with rational coefficients.-Martin Alander: A property of meromorph functions at the interior of a line of constant modulus—(i. H. van den Dungen: The calculation a priori of the vibrations of bending and other vibrations -Andre Défour. The utilisation of the tides —André Charrueau: The figures of equilibrium relative to a liquid mass in rotation, to the Newtonian attraction between its particles and to the surface tension.—J Ubach: Observations of the eclipse of the sun of Jan. 3, 1927, at Buenos Ayres (Argentine Republic). 94 photographs, 81 of which could be utilised for measurements, were taken under very favourable conditions. -Robert Esnault-Pelterie and Osée Marcus theoretical electrical resistance at the contact of two elastic conducting spheres, disregarding the passage layer—Emmanuel Dubois . The Volta effect. If a metal is heated in a vacuum, it is found after cooling that the heating has rendered it electro-negative, provided that the heating has been sufficiently prolonged and carried out at a sufficiently high temperature From the experiments given it would appear that the variations in the electromotive force obtamed after heating an electrode in a vacuum arise from the disappearance of impurities common to all metals — Rouelle: Certain peculiarities of ferro-resonance when the resistance is not negligible.

—E. Pierret: The Barkhausen oscillations obtained with French valves.—Nicolas Perrakis: The magnetic properties of vanadyl chloride and sulphate and the atomic moment of tetravalent vanadium. experiments cited prove that VIV possesses at least two atomic moments, one of 8 and the other of 9 magnetons. — Jacob: An experimental method permitting the comparison, at a given moment, of the velocity of light in one sense and in the opposite sense. — Duffieux: The production of the continuous spectrum of mercury by rotation in a vacuum. A detailed account of the phenomena observed when a drop of mercury is placed in a spherical evacuated glass globe, maintained in rotation (120 to 180 turns per minute), and the temperature slowly raised to a maximum of about 200° C -G. Reboul: The production of X-rays without a focus tube.—E. Darmois: The rotatory power of tartaric acid in solution in calcium chloride.—René Audubert: The application of the radiochemical theory to solutions of sodium iodide.—W. Kopaczewski and W. Szukiewicz: The rôle of some physical factors in the electrocapillary penetration of coloured colloids.—A. Boutaric and G. Corbet: The critical temperatures of solution of

mixtures of alcohol and some hydrocarbons. method given, specially designed to deal with mixtures possessing a low critical temperature of solution, was used to show that although benzene and pure alcohol are miscible in all proportions, contrary to the view generally held, petrol and absolute alcohol are not miscible in all proportions.—Eugène Cornec and Paul Klug. The boiling of saturated solutions, a method of physico-chemical analysis -F. Bourion and E. Rouyer. The sensibility of some test papers towards gaseous phosphoretted hydrogen Papers containing silver nitrate or mercuric chloride are capable of showing the presence of 1 part in 1,000,000 of gaseous phosphine—C Dosios and G. Leucaditis: The mechanism of the formation of ketones during the dry distillation of the salts of organic acids. It is well known that asymmetrical ketones are produced by the dry distillation of mixtures of salts of two different acids, but the mechanism of the reaction has not been made out The hypothesis of an intermediate phase, the anhydride of the organic acid, is put forward The exchange of alkyl and aryl groups between a mixture of ketones at a high temperature does not appear to take place, but the acid anhydrides can, under the conditions of these reactions, exchange their characteristic groups -Charles Prévost: The tautomerism of two dibromides of an erythrene hydrocarbon. The preparation of the hydrocarbon dusocrotyl in a state of purity is described Bromine gives two dibrom derivatives, only one of which can be isolated. Attempts to prepare the fully saturated tetra-brom derivative failed.—Albert Kirrmann: The a-bromaldehydes. The a-halogen aldehydes react as though they contained acid halides, even after a bisulphite purification.—M. Tiffeneau and Mlle Jean Lévy The affinity capacity of the p-tolyl radical.—P. Fallot and R. Bataller: The north-east edge of the Cretaceous massif of Bas-Aragon.—E. Tabesse: Magnetic measurements in the centre and west of France. A table of the measurements is given, reduced to Jan 1, 1922 The distribution of the magnetic elements is generally normal, except in the Civray region, where there appears to exist a strong anomaly, principally for the declination -P. Idrac: A self-recording apparatus for the oceanographic study of deep currents. The apparatus described has been used experimentally on the coasts of Cotentin It is specially intended for use on the Pourquoi-Pas? for studying the fluctuations of the currents in the English Channel and on the banks of Rockall and Porcupine.—Pierre Gavaudan: The origin and characters of the oil-bearing elements of Madotheca platiphylla.—A Ch. Hollande: The renovation of the epithelium of the middle intestine of the Egyptian cricket, Orthacanthacris (Acridium) ægypta—Alphonse Labbé: The existence of specialised branchia in some copepods — M. and Mme Lapicque: The electrical reaction of plant cells and its relations with the excitability. A repetition of Waller's experiments that the blaze current is a sign of lesion; it is only a sign of life in so far as it marks the passage to death.—Mile M. L. Verrier: The

determination of the anatomical visual field in fishes and batrachians.—H. Labbé and A. Kotzareff: The action of mesothorium bromide on glycæmia in normal and cancerous mice.—Philippe Fabre: Neuro-muscular excitation by cuneiform waves.—Raymond-Hamet: The cardiac action of adrenaline during the stimulation of the vagus.—E. Roubaud. The eclosion of the egg and the stimulants of eclosion in the Stegomyia of yellow fever.—L. Lutz. The soluble ferments secreted by the hymenomycete fungi. Tannin as an antioxygen.—X Chahovitch, V. Arnovljevitch, and Mlle M Vichnjitch. The proteid sugar in various pathological states. Proteid hyperglycæmia is not a disorder specific to a disease, but is met with whenever there is some lack of nutrition and is the expression of the general metabolism changed by the influence of a non-specific agent.—A. T. Salimbeni and R. Sazerac: The action of bismuth on the spirochæte of Sodoku in the experimental infection of the guinea-pig.

#### ROME.

Royal National Academy of the Lincei, Mar. 20.— G. Fubini. The geometry of a surface in the projective group and in the conform group.—O. M. Corbino: Electrolysis without electrodes. In cases when electrolysis of a liquid is induced by an arc or an ionic discharge between an external electrode and the liquid, the lack of a metallic electrode not only changes the form of the cathodic deposit, which may assume the colloidal state, but also the chemical character of the electrolytic process may undergo modification. This is shown by the liberation of hydrogen rather than the deposition of metallic gold from a gilding bath.—A. L. Herrera: Growth and multiplication of artificial amœbæ. These structures, formed by drops of sodium hydroxide solution in a mixture of light petroleum and olive oil, are able to exhibit, although only to a limited degree, the phenomena of growth and multiplication, owing to increase of the osmotic pressure by absorption of fresh quantities of oil dissolved in petroleum through the soap membrane surrounding the alkaline drops.-E. Bompiani: Some general ideas for the differential study of [geometrical] varieties.—E. Bortolotti: Axial systems and connexions in  $V_m$ .—W. Blaschke: The linear element of Liouville.—G. Andreoli. Curvature and parallelism in a surface.—S. Cherubino: The integration of linear differential forms.—J. Dubourdieu: The holonomy groups of Riemann spaces of four dimensions. Case of an Einstein  $ds^2$ .—V. Hlavaty: Contact of two curves in a  $V_m$ .—L. Laboccetta: The analytical representation in finite form of the magnitudes expressed by different functions in arbitrarily assigned regions of the plane and of space.-N. Spampinato: Further contributions to the general theory of Riemann's matrices.—M. Pascal: Curves for the maximum (or minimum) thrust [aerial].—G. Todesco: Investigations on the accidental thermoelectricity of bismuth. Majorana's experiment with an amplifier and a thermionic valve demonstrated the possibility of obtaining a sound in a telephone connected with the amplifier if the latter is joined to a flat coil of high resistance having as nucleus a bismuth disc or ring, one of the faces of which is exposed to luminous radiation, periodically interrupted. The dissymmetries which cause this accidental thermo-electricity of bismuth are due merely to the fact that, in the crystallisation following fusion of the metal, the elementary crystals are disposed in the mass of the metal with varying orientation, contact of differently inclined crystals resulting in the formation of thermo-electric couples.-G. Piccardi:

Isotopy, excess weight, and atomic structure. According to a hypothesis previously advanced, an atomic species of number N and atomic weight P should possess (P-2N) positive electrons and (P-2N)negative electrons external to the atomic nucleus and arranged to form an electrically neutral whole. This hypothesis is now supported by the relations, manifested but as yet incompletely studied, between the atomic weight and (1) the difference between the weights of the lowest and highest isotopes, or the field of variability of the isotopes, for each element, and (2) the maximum excess weight exhibited by any group of isotopes.-D. Bigiavi: Relations between aromatic nitro-derivatives and azoxy-compounds. Evidence is adduced which confirms the reluctance to undergo substitution exhibited by the aromatic nucleus contiguous to the pentavalent nitrogen of the azoxy-compounds, and moreover shows that, in general, the presence in the aromatic nucleus of an azoderivative of nitro-groups in the para- or orthoposition to the azo-grouping renders difficult the addition of oxygen to a nitrogen atom of the azo-group by means of peracetic acid.—G. Malquori: The system  $\mathrm{Al}(\mathrm{NO_3})_3$ .  $\mathrm{KNO_3}:\mathrm{H_2O}$  at 25°. The isotherm of this system for the temperature 25° fails to indicate the formation of an additive compound between the two nitrates.-P. Pasquini: Homeoplastic grafting of the ocular rudiments in embryos of Pleurodeles Waltli.-R. Savelli: Lack of confirmation of the Giglio-Tos 'rational laws' on hybridism.

## Pure Chemistry: a Report and its Implications.

FROM time to time in these columns the necessity for a new orientation of educational thought has been stressed. We have pointed to the changing intricacy of modern life—quickened, illuminated, ennobled, and enriched by the practical application of many sciences—and have frankly stated the view that, unless the new aspects and forces be deliberately woven into our educational schemes, those schemes are foredoomed to failure.

It is our business, however, sedulously to avoid being carried away by any theory which will not submit to all possible tests. All the many facets which a single problem may present must be taken into consideration. We do not imagine, for example, that one successful experiment necessarily presents a sound reason for sweeping and immediate alterations to some industrial process which rests upon conditions not always apparent in the laboratory

Such considerations compel us to realise that the educational changes we have in mind cannot be made impetuously. Time is necessary for the formation of professional no less than public opinion. Environmental factors need adaptation. If, for example, we have urged greater attention to technical education, not only as a sine qua non of industry but also as a vehicle of liberal qualities as yet but dimly apprehended, we have not failed to observe that its success is as much dependent upon its relationships with other forms of education and with industry as it is upon administrative method and teaching power. Is there any proof that advance in these directions is being made?

An encouraging answer is to be found in a Report 1 concerning the provision of chemical instruction in technical institutions, recently issued by the Board of Education. We congratulate the compilers on a brief and excellent piece of work. In the sober and guarded language of an official report, they have done something more than sketch out the volume and character of the provision of instruction in pure chemistry in English technical schools; they have done something more than set out important statistics and comment on the general standard of the work They have shown clearly the influence of factors upon which we have frequently insisted. They have presented undeniable evidence of definite advance as a result of those factors; and, in spite of their assertion

<sup>1</sup> Report of H M Inspectors on the Provision of Instruction in Pure Chemistry in the Technical Colleges and Schools in England. Pp 11. (London H M Stationery Office, 1927) 3d. net

that only pure chemistry is under review, they have, by implication, described the way of further development in other subjects

Notice the result of wider secondary education (in the full meaning of the term) and the growing appreciation of employers of the instruction available. It is now expected that, before admission to a full-time course a student should have received a secondary school education, though matriculation is not essential students entering part-time courses need not have been through the ordinary secondary school, but are expected either to have passed through a junior technical course consisting of mathematics, science, drawing, and English, or to show they have some knowledge of these This improvement is not due solely subjects to the wider provision of varying types of secondary education, but also to "the growing practice of employers in requiring that candidates for junior positions in their laboratories shall have received a superior type of education "

Well-organised evening courses, too, are playing a part which is of especial importance when it is noted that, of the 11,000 students taking instruction in pure chemistry, only about 15 per cent. are in full-time attendance (at 32 institutions). In 163 institutions, however, instruction is provided in part-time grouped courses. Insistence is now possible on an adequate standard of training preliminary to admission to evening junior technical courses. "As a consequence a higher standard of attainment is now secured in respect of an increasing number of part-time students"

Active interest on the part of employers and better preliminary training cannot, however, produce this higher standard of attainment unless administrative and co-ordinating factors also receive attention. By no means small have been the parts played by examination arrangements. "In the north-west the influence of the Union of Lancashire and Cheshire Institutes has been operative: in the midlands and the south the attraction of a University degree has been more important . . . in Pharmaceutical courses, the new requirements of the Pharmaceutical Society have increased both the numbers of students and the systematic character of their studies." This question of examinations—a vital function in the educational process is, in its wide implications, still under discussion in connexion with most branches of technical education, and there can be no doubt that the National Certificate schemes have gone far to satisfy supporters of the purely internal and of the purely external systems. Nor have examinations and new requirements fallen with dead and levelling weight upon the institutions "This degree of organisation has been secured without depriving the schools of their individuality"

If any more definite measurement of all-round improvement be necessary, the following extract can scarcely be bettered "A few years ago the proportion of students attending courses was probably not half what it is now The standard of admission was lower and less clearly defined, and a large number of students were entering upon the study of applied Chemistry with totally inadequate grounding in Pure Chemistry and with no previous or concurrent instruction in Physics" Now nearly eighty per cent of part-time students take courses involving attendance on three evenings per week and including the subsidiary subjects of mathematics and physics There is also a growing tendency to prepare for the associateship of the Institute of Chemistry in both full- and part-time courses

Though, however, the organisation may be excellent, the success of the work must ultimately rest upon the teacher—the final executive officer. In this connexion again the Report is soberly confident. The main work is in the hands of the permanent teachers of the technical school, who are assisted in the evening work by teachers who are employed in the day time in Secondary, Junior Technical or Central Schools, or in industry very large proportion of both groups possess graduate or equivalent qualifications general standard is therefore high, and is almost in itself a guarantee of the fullness and accuracy of the instruction" Some points of criticism arise, however, which give an indication of the special qualities which are needed in technical teaching—qualities not always found in teachers trained along the usual academic lines. "Some teachers who have had experience with young students cover the ground too slowly for the older students who attend evening classes, and they waste a good deal of time endeavouring to clicit conclusions from early and isolated experiments." The use of text-books, too, is not always understood. "Students need to be trained to acquire information for themselves, and the lecture hour is often more profitably devoted to emphasismo important points—creating perspective [our italics] -than in conveying information which can be obtained quite easily from a book"

A broad classification of 10,379 students for mg part-time courses is given. Within the chemical industry 2450 are engaged in laboratory

work, 1309 in the factory, and 651 in clerical or commercial work. 2324 are engaged in retail pharmacy and dispensing, while 3645 are absorbed by "other occupations" These figures give peculiar significance to another valuable point to which the Report directs attention In some schools "insufficient training is given in the simple laboratory operations The students have not enough practice in fitting up apparatus, and the importance of neatness and tidiness is not sufficiently impressed upon them" We have already noted a not dissimilar criticism in a speech made to the Association of Teachers in Technical Institutions by the ex-president of the Society of Chemical Industry (NATURE, June 25, p 942)

We hope in observing these defects we do not give any wrong impression We asked, at the outset, whether any proof was available concerning our own expressed views on the new factors which are slowly to change much current educational theory The Report provides us with adequate proof, and we shall bear its principles in mind in reviewing subjects other than chemistry In the meantime, so far as the latter is concerned, the crisp conclusion of the Report stands in need of no adornment "The teachers as a body are well qualified and generally competent, the accommodation and equipment are, on the whole, good, the organisation of most of the courses is satisfactory, and the defects to which attention has been drawn are the exception rather than the rule"

### X-Rays and Contemporary Physics.

- (1) X-Rays and Electrons. an Outline of Recent X-Ray Theory By Prof Arthur H Compton. Pp xv + 403 (London Macmillan and Co, Ltd, 1927) 25s net
- (2) Introduction to Contemporary Physics By Dr. Karl K Darrow Pp xxv1+456 (London. Macmillan and Co., Ltd, 1927) 25s net
- (1) THE rivalry of classical wave theory and modernist quantum theory has of late years dominated the physics of radiation, and in spite of all our efforts we can scarcely say that a really satisfactory solution is yet in sight where is the conflict more acute than in the field of X-rays, and the investigations of the past few years have all gone to emphasise the differences rather than to reconcile the warring interests. On one hand we have the establishment of what might be called the optical properties of X-rays,

through a prism, phenomena hitherto always explained in terms of the wave theory: on the other hand, quantum effects of an extreme type have been revealed by the study of the extraordinary effect known by the name of Compton, who first established that for very short X-rays, where the quantum of energy is large, the radiation can be shown to behave in many respects like a minute projectile, the results of whose impacts with an electron can be calculated on the lines of the impacts of massive spheres Prof Compton has also been closely interested in many problems which have been worked out in terms of the wave theory, such as the questions of the intensity of X-ray reflection and of X-ray absorption. His recent book on X-rays and electrons has therefore strong claims on our attention.

Prof Compton's book is, broadly speaking, devoted to the discussion of experiments and theories bearing on the physical nature of X-rays, and comparatively little is said of their applications either to the study of crystal structure or to practical questions such as the investigation of fibrous forms, organic or metallic. Much of the first part of the book is devoted to physical problems of which an explanation can be attempted in terms of classical electromagnetic theory, such as the polarisation of scattered X-rays, the intensity of X-rays reflected from crystals, and the more strictly optical properties of X-rays. Within the last few years, X-rays have been diffracted by ruled gratings, chiefly by Compton and Doan, and by Thibaud, and a striking photograph is given of a spectrum so obtained. Of course, the accuracy to be expected with this method does not so far approach that obtainable with ordinary crystal methods, but a value for the wave-length of molybdenum Ka has been obtained which agrees exactly with the crystal determination

A special chapter is devoted to the refraction, in the ordinary optical sense, of X-rays, and the small deviation from Bragg's law  $n\lambda = 2d \sin \theta$ , which has been experimentally detected, is explained in terms of the refractive index, which calculation shows to be slightly less than unity The total reflection at small glancing angles to be expected from such a value of the index, and the refraction by a prism of glass established by Siegbahn and others, are illustrated by excellent photographs. As Compton emphasises, the experimental determination of the refractive index affords a straightforward method of determining the total number such as reflection at a glass surface and refraction rof extranuclear electrons, and the value so found agrees closely with the atomic number. As is natural, the book contains full references to recent American work, such as Hewlett's repetition of Barkla's work on the scattering of soft X-rays which, on the basis of J. Thomson's classical theory, also gives very satisfactory values for the number of electrons in, for example, the carbon atom

The questions of the intensity of reflection of X-rays from crystals and the closely allied questions of absorption are treated in much greater detail than has so far been attempted in any book in The well-known work of W L Bragg and his collaborators, and the theoretical treatment of the whole problem by C G Darwin, are discussed at some length, and recent work by the author and his collaborators and other American workers, which is not yet widely known, is described Prof Compton has devoted much research to this part of the subject, and the various aspects of the somewhat complicated phenomenon of primary and secondary extinction come up for treatment. The distribution of electrons obtained by W. L Bragg and by the later American workers depends, of course, upon the laws of classical electrodynamics, and it is not established beyond doubt that they form a valid basis for such calculation.

The mability of the classical theory to explain the scattering of hard X-rays is well known, and Prof. Compton's account of his discovery of quantum scattering and the researches which have followed it, especially in America, will be eagerly read The quantum theory of the change of wavelength which accompanies the scattering of hard X-rays by 'free' electrons is very simple, and the general features—change of wave-length with angle of scattering, directed scattered quantum and recoil electrons—have been clearly confirmed by experiment. In this field the Wilson cloud chamber has proved its value as an instrument of investigation in a number of daring experiments. When we try to go a little farther, however, the initial simplicity is quickly succeeded by complications and difficulties The calculation of the broadening of the unmodified line demands some hypothesis as to the behaviour of the electrons within the atom, that is, we have to take into account the orbital motion of the electron at the moment when it is 'struck' by the quantum of radiation, and Jauncey's calculation on these lines is only partially satisfactory. The intensity of the scattered X-rays takes us still farther into doubtful and difficult fields. Here we may hope for the new quantum mechanics, out of which the

Compton effect comes so naturally, to give us some acceptable solution

The points mentioned are chosen from among some of the most interesting, and do not exhaust the scope of the book. There is, for example, a chapter on familiar lines dealing with X-rays and crystal structure, and another dealing with the elegant and less-known method of treating diffraction by a crystal from the quantum point of view.

The treatment in the book is largely mathematical, and greater attention is paid to the theories than to the description of experiments for example, the account of Compton and Simons' striking cloud experiment on the direction of the scattered quantum is very meagre, and less clear than the short description given by Kallmann and Mark in Ergebnisse der Naturwissenschaften. Naturally, the work of American investigators receives great prominence, to the relative exclusion of German work The work of the last few years is really the subject of the book, so that it often happens that partially unsolved problems and incomplete investigations are treated at great length. This actuality of the book will enhance its value to all those engaged in research in these difficult regions, but sometimes renders it tough reading

The general production is excellent, but it is unfortunate that the proof-reading has not been more carefully carried out. The literal misprints are many, but need not trouble the reader, as it requires, for example, little ingenuity to see in Naturious a reference to Naturunssenschaften, or to see that by  $I\lambda$  is meant  $I_{\lambda}$ . When it comes, however, to being referred back to Fig. 4.05 and finding that it means Fig 45; to page ix. 23, and having to discover that it means page 280 in chapter ix.; to page 22 when page 241 is meant. and so on, the reader grudges the waste of time. The index is incomplete even beyond the worst of indexes, and may give a false idea of the scope of the book: for example, the names of Dirac, Kuhlenkampff, Ishino, and many other workers do not occur in it, although there are references to their work in the book. These blemishes, however, are minor defects, which should not damp our appreciation of a book in which a great investigator gives an account of some of the most striking recent investigations in physics, of which he himself has been a great part.

(2) The reports on contemporary advances in physics, published by Dr Darrow in the *Bell System Technical Journal*, and distributed in separate form, are known to many physicists:

Dr Darrow, who is a member of the staff of the Bell Telephone Laboratories, has now brought out a book based on them. The "Contemporary Physics" of the title refers to what may be called the physics of atoms and rays, and no attempt is made to cover the whole field of physics Within the range chosen, Dr Darrow has made an excellent selection of material, which includes much important American work not hitherto quoted in text-books. The disconnected nature of the original articles, each of which referred to some one topical branch of investigation, has not been entirely eliminated in the book, so that we find some overlapping, and an order which must sometimes prove disconcerting Thus ionisation and radiation to the student potentials are discussed in Chapter vii, while clastic and inelastic impact are first defined in a subsequent chapter, and an account of Bohr's atom model is given still later The final chapter, which follows the epilogue, is a practically independent dissertation on the conduction of electricity through gases. The separate chapters make very interesting reading, for the author has picked out for treatment the phenomena on which attention is chiefly concentrated at the present time, and the book is embellished by a number of pertinent photographs illustrating various features , of modern work on spectra, which are not, however, very clearly reproduced in some cases

Dr. Darrow's book, like Prof. Compton's, serves to remind us of the enormous amount of purely scientific work now being carried on in great laboratories of America, both those of universities and those attached to great commercial concerns.

### Yield Trials in Agriculture.

The Principles and Practice of Yield Trials. By F L Engledow and G Udny Yule. Pp. 78. (London The Empire Cotton Growing Corporation, 1926) 2s.

It is now nearly twenty years since a considerable number of agronomists in Great Britian have reached the opinion that agricultural field trials, whether concerned primarily with manures or with varieties, if they were to afford practical guidance to the farmer, must be carried out with increased precision. The important preliminary work of exploring the variability of yield by uniformity trials was performed for England in two excellent investigations by Wood and Stratton at Cambridge and by Mercer and Hall at Rothamsted. At about the same time, by what is not necessarily a co-

merdence, a fundamental advance in the theory of errors, which renders possible the exact treatment of the evidence of small samples, was made by that anonymous genius who disguises his identity under the pseudonym of "Student" Since that time the work of applying the knowledge gained to the practical refinement of agricultural experimentation has been actively carried on by Dr. Beaven at Warminster, and more recently in the Statistical and Field Department at Rothamsted, it would scarcely be an exaggeration to regard "Student" as the spiritual father of both developments

The recent memoir by F L Engledow and G Udny Yule on the Principles and Practice of Yield Trials" represents another case of the cooperation between the statistical and the experimental phases of the same large problem It is divided into two sections, of which the first includes an explanation of the statistical methods advocated, while the second deals with ' practical considerations and procedure." Commencing with Mercer and Hall's data in their uniformity trial with wheat, the reader receives a clear explanation of why an experiment, comparing the yields of single half-acre plots, may be expected to yield errors of the order of 5 per cent; and of how much higher accuracy is attained by utilising the same area under smaller replicated plots A statistical treatment is given for replicated plots, and a table of the normal distribution is provided and its use explained for finding the probability of exceeding by chance a given multiple of the standard error as estimated. Theoretical and practical limitations of the formula are then discussed, the principal of the latter being that ascribed to the differential response of varieties to climatic variations

In the second portion we do not hear so much of " practical considerations " as we might have hoped from the title, for the authors devote most of the available space, as they naively say, "to explain broad questions of policy," so that we are left much in the dark as to their opinions on many practical Only variety trials are discussed, and details these only with cereals The treatment is less systematic than that of the first part, and we are seldom allowed to forget, for more than a few paragraphs, how comparatively unimportant the author considers yield trials in general, and in particular the improvements in accuracy of which they are susceptible It is difficult to summarise this section. The first three portions seem designed to assert, at some length, that (i) varietal differences in quality are often more important than yield; (ii) qualitative differences should govern the choice of varieties for yield trials; (iii) the significance of yield-trial results is limited by their not being performed by industrial farm methods.

The fourth, fifth, and seventh portions are devoted to observation plots, an important subject, upon which the author speaks with authority, but which unfortunately can scarcely provide a preliminary opinion as to yield, much less a measure of it. Yield trials on the plan denoted 'chessboard 'are most carefully described; it should be noted that the author limits this extremely vague term to small trials carried out under a wire cage, with individual seeds dibbled at regular intervals, on a fine tilth; the 'plots' are about a yard square The reader of this portion will realise the force of the strictures previously developed upon the limited agricultural significance of trials, which depart from the methods of practical farming, but will wonder why no distinction was there made between 'chessboard' trials of this type and the betterknown methods of plot replication in the open field. A second valuable portion is the description of Beaven's half-drill strip method. Unfortunately, this is the only field method discussed. The last two portions on the size and arrangements of plots, and on 'corrections' for soil irregularities, have perhaps been hurriedly written, and without any very full consideration of the subject.

The authors have missed the fact that the method developed, following "Student," in Section I., is equivalent to a method of 'corrections' stigmatised on p. 75; as, indeed, is necessarily any method of eliminating a portion of the soil heterogeneity The fact also, that "Student" had shown eighteen years before that precise values of the probability may be obtained in tests of significance with small samples, is overlooked on p. 77, where it is asserted that "in agricultural work with a very small sample (e.g. of four or five observations) the value of P, however obtained, is quite untrustworthy." criticism should of course be confined to the methods here expounded; the great beauty of "Student's" treatment lies in the fact that it does give trustworthy tests of significance, within the scope of agricultural experimentation.

Apart from this omission, statistical criticisms will naturally be few. It appears unfortunate that in developing "Student's" method of treatment of a replicated experiment, the estimation of residual errors has been changed in such a way as to produce, in some cases, a serious under-estimate. A point, which is likely to be in some ways more misleading, lies in the use on p. 30 of the standard error appropriate to a pair of varieties chosen at random,

to test successive differences of a number of varieties set out in order of yield. This procedure is often grossly misleading, since the best and worst of a set of random yields from the same variety will often show 'significant' differences if tested in this way.

The curiously pessimistic tone as to the value of yield trials which influences both sections of the book is perhaps to be ascribed to a somewhat unexpected limitation of outlook as to the scientific purposes which such trials serve. After giving reasons for thinking that the differential response of varieties grown in different years may be so much as 5 per cent, a figure which the reviewer does not consider exaggerated, the authors continue (p. 33):

"In view of such results, it may well be asked, what is the value of these elaborate tests? The answer, though it may seem pessimistic to some, must be, we think, that it is very little or, if the phrase is preferred, extremely limited. Even in so far as the investigator is concerned with yield alone—and usually he is equally concerned with other qualities—he is concerned with the average relative yields over successive years."

It does not seem to have occurred to either author that a knowledge of these differential responses to weather or soil would itself be of extreme agricultural importance in the practical choice of varieties; and that such knowledge would do much to remove the real grievance of innumerable farmers who grow, for example, wheat in the west, or turnips in the south, of England, far from the centres of the industry, where research is properly concentrated. On the contrary, both effects are looked upon merely as 'errors' to be averaged out by interminable repetition. This same consideration of differential weather responses evidently also underlies the numerous passages decrying attempts to increase accuracy.

To adduce the importance of qualitative differences as a reason for neglecting accurate yield trials appears to the writer at least equally farfetched. After all, the demand for higher yielding varieties comes straight from the practical farmer, and, however difficult the experimenter may find it to attain adequate accuracy to meet this demand, it is a mere evasion of the difficulty to discant upon the importance, which no one denies, of qualitative differences. How the practical adviser is to weigh qualitative advantages against a loss of yield, or vice versa, without an accurate knowledge of the yield factor, is nowhere explained.

For these weaknesses it is probable that neither author would be to blame had the book been published either earlier or later by a few years; a few years ago, the theory on which the Latin Square

and other 'randomised' systems are based had not been developed, and in a few years' time the lessons learnt from their use, whether more or less favourable to these methods, will be sufficiently well known, even to writers without personal experience of their working At the moment they are in the difficult position of judging of the newer developments in experimental theory and technique, by the standards of an older theory and technique, the defects and inconsistencies of which it is the avowed purpose of the newer methods to correct. It is the paradox of the present situation that cotton growers overseas should be putting into practice the applications of just these newer theoretical developments, which their academic mentors would have them regard as impracticable

R. A. FISHER

# Physical Chemistry and Geological Problems.

Physico-Chemical Geology By Dr R H Rastall. Pp vii + 248 (London. Edward Arnold and Co., 1927.) 15s. net.

IN recent years the empirical descriptive methods of an older generative. of an older generation of petrologists have been fortified by exact experimental work in fields of high temperatures and pressures; and some knowledge of the more notable results that have been achieved, and of the fundamental principles of physical chemistry on which they are based, has now become an indispensable part of the equipment of a modern petrologist. The steady stream of publications from the Geophysical Laboratory at Washington, and from various European workers such as Vogt and Niggli, indicates the increasing importance of chemical thermodynamics in revealing the processes which rocks have undergone. Hitherto, however, there has not been in English any systematic introduction to physical chemistry in its application to geological problems. Dr. Rastall will earn the gratitude of a wide range of students by providing this excellent foundation for more extensive studies.

The first four chapters deal with the basal conceptions of equilibrium and the phase rule, and with the phenomena of fusion and solidification, solution and crystallisation, isomorphism and polymorphism. The principles having been clearly established and illustrated by cogent mineralogical examples, the author passes on to their application to igneous rocks. These are polycomponent systems, so complex that a satisfactory phase rule discussion is generally out of the question. Never-

theless, the ternary systems embraced in the group of components  $SiO_2$ —MgO—CaO— $Al_2O_3$ , and the systems albite-anorthite, diopside-plagioclase, and orthoclase-silica, all of which have been worked out fairly completely under anhydrous conditions, have made it possible to consider some of the simpler magmas and their cooling histories with very successful results.

Little is known as yet of the quantitative effects of volatile fluxes, though preliminary work in simple cases with water and carbon dioxide as the volatiles has already encouraged the geophysical workers at Washington to more ambitious attempts to conquer this difficult field. It is probably here that the most brilliant conquests will ultimately be made, for already Th. Vogt has shown that the pneumatolytic and hydrothermal stages in the cooling of a magma can be explained on physicochemical grounds. Moreover, increasing attention is now being given to the separation and transfer of gaseous phases as an active process in causing differentiation, facilitating assimilation, promoting metasomatism and concentrating ores. These topics are still largely confined to more or less speculative discussions of field observations, and, perhaps rightly in an elementary book, Dr. Rastall has touched on them but sparingly. His discussion of differentiation, however, clearly shows that, despite the work of Brögger, Harker, Bowen and many others, the mystery of the general problem still remains to be solved. Dr. Rastall puts his finger on the core of the difficulty when he writes: "There is no experimental evidence at all in support of the theory that a silicate melt tends to split into two conjugate solutions. Nevertheless many of the facts of Nature indicate pretty clearly that something of the sort does occur."

It is suggested that there is no justification for the recognition of the *spilitic* suite of rocks on the ground that its members differ from the 'true alkaline rocks' only in having soda in considerable excess of potash. But they appear in a totally different structural environment from typical alkaline rocks, and if Shand's clean-cut definition of the latter be accepted, then most spilites are not technically *alkaline* at all. The recognition of a *spilitic* suite should not be described as an attempt to confuse the issue (p. 95), rather, it is an attempt to clarify an issue that is at present excessively confused.

The integration of processes described as metamorphism is next treated. Here many mineral associations are clearly deducible from the phase rule; but where differential pressure has operated,

the natural conditions again rapidly pass out of the present scope of experimentation. Thermodynamic principles lead to the important deduction that differential pressure lowers the melting point. This curious fact, so remarkable to the beginner, has endless applications, and it is a disappointment to find it merely stated without a graphical demonstration.

Weathering is very properly separated from metamorphism, for its processes involve the reactions of aqueous solutions in an environment of low pressure and fluctuating but relatively low temperatures. Despite the apparent simplicity, the conditions are tantalisingly complex from the point of view of physical chemistry. The peculiar properties of surfaces, capillary spaces, and colloids (the last briefly treated in the final chapter) all require fuller investigation, and still further complication is introduced by the uncertain influence of bacterial activity

Little reference is made to the conditions that control the cementation of sediments and the growth of concretions. This is a subject that has been strangely neglected, and a systematic treatment in a book of this kind would be widely appreciated. The precipitation of saline deposits from surface waters is, on the other hand, a subject that has been thoroughly tidied up, thanks to the familiar investigations made by Van't Hoff and his colleagues. The results are briefly reviewed in a chapter on salt deposits, in which is also included an account of the origin, still vaguely understood, of the carbonate formations, including dolomite. The two remaining chapters are devoted to ore deposits and refractories and abrasives, branches of economic geology on which Dr Rastall speaks with the personal authority of a wide experience.

Dr. Rastall has skilfully avoided the tempting atmosphere of speculation. He has surveyed his subject with commendable restraint, and produced a clearly written and trustworthy book which reveals both the strength and the limitations of the methods of physical chemistry. To know that the natural interplay of energies in the earth is too complex for complete imitation is a mental tonic rather than a cause for depression. To know that laterite, dolomite, lamprophyres, and many another puzzling rock still present baffling problems to be solved, merely adds to their fascination; and when all is said, one feels, after considering the subject matter of this book, that Sederholm is thoroughly justified in his insistence that geology is very much more than applied physics and chemistry. ARTHUR HOLMES.

### Biological Philosophy.

Theoretical Biology. By J von Uexkull. Translated by Dr D. L. Mackinion (International Library of Psychology, Philosophy, and Scientific Method.) Pp. xvi + 362. (London · Kegan Paul and Co, Ltd, New York. Harcourt, Brace and Co, Inc., 1926) 18s net.

THE publishers of the International Library of Psychology, Philosophy, and Scientific Method are to be congratulated not only on the inclusion in their collection of this peculiarly interesting addition to biological thought, but also on securing the services of such an able translator Reference to Dr D L. Mackinnon's name on the title-page is necessary before the fact of translation is realised.

In this "Theoretical Biology," von Uexkull discusses modern biological concepts, and summarises them in relation to his extended application of Kantian philosophy to the animal world. Biological science has come to a deadlock by having been too greatly dominated by the physicist's insistence on an objective world, whereas the true secret of understanding is to be found not behind objects but subjects. The observer's viewpoint must of necessity be outside this subjective world, and when this fact is clearly realised, investigation can proceed

The mechanical processes of the organism reveal a conformation to a rule of Nature, which is not merely a mechanical law, but also indicates that there is a super-mechanical factor at work the production of a new framework, a process which takes place within every cell, repair proceeds from within. In a machine, this need for reconstruction must be dealt with from without, therefore here is an example of this super-mechanical factor, or 'impulse,' as von Uexkull calls it sion of a cell by impulses is always followed by the formation of a new framework, and consequently the impulses are referable to an influence exerted by the genes on the protoplasm. These impulsesystems are not regarded as a 'psychical worldfactor'-on the contrary, von Uexkull anticipates their isolation, since already there are indications that transference of form-giving impulses can take place. Thus they are part of an "objective conformity with plan," a biological doctrine into which "Lamarckism would pass straight over, would it but throw off its psychological wrappings." There is no question of 'purpose' or 'purposefulness,' as is generally understood by the idea of 'conformity with plan.' von Uexkull deplores the fact that the personification of Nature, which conception has occupied the minds of men for so long, cannot be dismissed once and for all from the realms of biological thought, and with it the inability to recognise "limits to the possibility of knowledge," so that full attention can be given to the acquisition of those positive additions to knowledge by means of which alone real progress can be made.

H. E. B.

### Enzymes.

Enzymes Properties, Distribution, Methods and Applications. By Prof. Selman A. Waksman and Prof Wilburt C. Davison. Pp. xii + 364. (London Baillière, Tindall and Cox, 1926) 25s. net.

THE authors of this book state that it has been their endeavour to collect in as concise a form as possible the available information in regard to enzymes and to indicate the original sources from which more detailed knowledge may be obtained. To piece these irregular and loosely fitting fragments together has been their object. Special attention has, they say, been paid to the occurrence and preparation of enzymes, to the methods of the measurement of their activity, and to the practical application of these agents

The text is divided into four sections, each of which is subdivided into chapters as follows.

(a) Properties of enzymes (four chapters); (b) distribution of enzymes (three chapters); (c) methods for the preparation and study, of enzymes (seven chapters); (d) practical application of enzyme activity (one chapter).

There is a bibliography giving references to 1323 original papers, none of which, however, is later than 1925. The book is brought to a close with an index.

The introductory chapter gives an outline of the history, general characteristics, nomenclature and classification of enzymes. The next three chapters deal with chemistry, biology, and physics. The major portion of the next chapter is devoted to the occurrence and distribution of enzymes in animal secretions and tissues. This is followed by two shorter chapters on the enzymes of the higher plants and of micro-organisms.

The section commencing with Chapter viii is the longest in the book, covering as it does 128 pages of text. Although containing some most useful information, clearly set forth and well arranged, it is here that we venture to make some criticism Under methods of measuring diastatic action, the authors describe Wohlgemuth's iodine method and Lintner's saccharometric method. In regard to the latter, a modification is described which is more complicated and does not appear to lead to

mcreased accuracy. No mention is made of the titration method devised by Prof. A. R. Ling, which has been adopted by the Institute of Brewing as one of the standard methods of malt analysis. Nor is there any mention that when the activity of malt diastase is measured by a saccharometric method, the production of reducing sugar must be kept within the limits laid down by Kjeldahl in 1879 if the results obtained with two or more samples are to stand in direct proportion.

In dealing with the synthetic action of enzymes, the work of Bourquelot-by far the most important on the subject—is not alluded to in the text. In that part of the book dealing with desmolasesoxidases, oxido-reductases, and zymases-sometimes the difference between supposed direct oxidase action and dehydrase action is described m a manner likely to prove misleading to the student. The authors make no reference to the discovery by Hopkins in 1921 of an autoxidisable constituent of the cell which he named glutathione, although they do refer to the significance in respiration of substances containing the thiol group SH which is present in reduced glutathione. Another serious omission is that of a reference to the recent work of Robison on the part played by calcium hexosephosphate and its enzyme on ossification and dentition.

If there are defects in the preceding parts of this book, there are more pronounced cases in the last chapter which deals with the uses of enzymes. Barley is said to absorb 40-50 per cent. of its weight of water in the steeping process—the first in the conversion of barley into malt. The fact is that barley after steeping contains about 50 per cent. of water. In describing the mashing process the temperatures given are 23°-13° C. too low for distillery practice and 26°-16° C. too low for brewery practice. The subject matter on the hydrolysis of starch by enzymes given in the book is out-ofdate, as is also that dealing with the estimation of starch by enzymes, and the latest methods adopted in England find no mention. These are only a few of the defects which could be cited.

We close our review with a feeling of disappointment Some portions of the book are such as to recommend it, whilst others show that the authors have omitted important observations or have failed to understand the true significance of some points to which they have referred. It is hoped that a new edition will be published in the near future in which the entire work will be recast, for the authors have not attained the objects which they set themselves to achieve.

### Our Bookshelf.

Practical Coal Production. Mine Transportation and Market Preparation: Mine Transportation, Hoisting and Hoisting Equipment, Coal Preparation. Compiled by Frank H. Kneeland. Pp vii +354. (New York: McGraw-Hill Book Co, Inc.; London: McGraw-Hill Publishing Co., Ltd., 1926.) 15s. net.

This volume is the third of the series of "Practical Coal Production" and may be looked upon as a continuation of the two previous ones, which have already been discussed in these columns. The present volume is no advance on its predecessors, showing quite as strongly as they do the defects previously indicated, and being perhaps even more scrappy' than either of the others. It contains three chapters, on mine transportation, hoisting and hoisting equipment, and coal preparation respectively. The first part consists of a miscellaneous collection of information concerning animal and locomotive transport underground; perhaps the best point about this section is the considerable attention paid to underground track work, the importance of which is just beginning to be recognised by colliery managers. Chapter ii. is almost wholly taken up by calculations, such important matters as the construction and design of cages and headgears not being even mentioned. Having regard to the recent developments in American coal mining, one would have expected to have found some information, at any rate, as to the employment of skips instead of cages, but this again has been entirely neglected. The third chapter is taken up mainly with coal conveying and screening. The author is aware of coal washing, but he dismisses it in a few lines, as though it were not in fact the most important part of coal preparation at the present day.

The author's lack of knowledge of what has been done in Great Britain again makes itself manifest at various points; thus he describes as an entirely novel invention screens, which he calls weightvibrated, being evidently unaware that the appliance he is describing is simply the old Beaumont vibromotor invented years ago in England. Whilst the book is well got up, misprints are more numerous than they should be. Perhaps the most noteworthy one is a caption on p. 3, "Insulting the Mule," when it is obvious from the context that the author

must have written "Insulating."

(1) Proceedings of the London Mathematical Society. Second Series. Vol. 25. Pp. 546. n.p.

(2) Journal of the London Mathematical Society.
 Vol. 1. Pp. 272. n.p.
 (London: Francis Hodgson, 1926.)

THE London Mathematical Society now issues its transactions in two volumes a year, the *Proceedings* and the *Journal*. Vol. 25 of the *Proceedings* contains 31 technical papers on various branches of mathematics read before the Society between March 1924 and January 1926. The high standard of recent issues is fully maintained, among the more

notable contents of this volume being Mr Chaundy's "Poncelet's Poristic Polygons," Prof Landau's "Zum Waringsche Problem," and Prof. Turnbull's "Invariant Theory of Mixed Quaternary Forms." Only a small number of papers deal with geometrical matters, an indication that most of the mathematical research now done in England is analytical rather than geometrical in character. Our only criticism is of the length of time, sometimes more than a year, which elapses between the reading of a paper and its appearance in the *Proceedings*.

Instead of the abstracts which have appeared in recent volumes of the Proceedings, the Society now issues a Journal, of which the first volume is before It contains records of the meetings held in the session 1925-6, three lectures given at meetings, and about fifty notes and short papers Prof Baker also contributes obituary notices of F. Klein and C. Segre, both being worthy tributes to the memory of distinguished mathematicians Of the lectures, Dr Glaisher's on the early history of the Society is the one of most interest to a general reader. Many of the short papers contain significant contributions to mathematical knowledge, Mr. Grace's "Point in Enumerative Geometry," Prof. Hobson's "Generalisation of a Theorem due to Riesz," and Prof. E. A. Milne's "Diffusion of Imprisoned Radiation through a Gas" being typical of many others showing marked progress in their respective fields. The publication of this new Journal has been rendered possible by the increased membership of the Society and also by the greater volume of noteworthy mathematical research produced in recent years. Either Journal or Proceedings can be obtained in parts as issued by non-members of the Society. W. E. H. B.

L'Atomisme d'Épicure. Par Dr Xénia Atanassiévitch. Pp. 111. (Paris: Les Presses universitaires de France, n d) n.p.

Dr. Atanassiévitch has written an interesting and well-documented study of the atomic theory of Epicurus, in which he maintains that, far from being a mere expounder of the theory of Leucippus and Democritus, Epicurus was responsible for the introduction of many new features. The number of fragments of Epicurus accessible to us is very limited, consisting mainly of a few letters, preserved for us by Diogenes Laertius, of which the authenticity is not established beyond doubt, but fortunately we possess what is probably a very faithful account of his theories in Lucretius' "De Rerum Natura." Leucippus, who is a merc name to us, and Democritus, whose work is also lost to us, supposed, according to their expounders, that atoms were indestructible and eternal, infinite in form and in number, and that everything arose from the collision of atoms in empty space. Epicurus denied that the atoms could have an infinite variety of forms, which agrees with our modern belief, and insisted that atoms had weight, which, according to Dr Atanassiévitch, was a property foreign to the atoms of Democritus. For Epicurus, then, atoms had size, shape, weight, and

velocity. Very interesting, in view of our modern theories, is the Epicurean doctrine. stressed by our present author, that, although atoms are physically indivisible, they have finite extension, and are to be considered as made up of small ultimate parts, minima. A chapter is consecrated to this doctrine of the minimum

It is very strange that, without any given experimental basis, often with ridiculous arguments—as when he cites spontaneous generation as a proof that atoms have no sensations—Epicurus should have arrived at a conception of the atom so similar in its essence to our present-day atoms built up of electrons. It would seem that there is something inherently attractive for the human mind not only in an atomic theory, but also in an atomic theory of a particular kind. Dr. Atanassiévitch's little book is well worthy of study by all interested in the history of scientific theories

E N DA C A.

Among the Kara-Korum Glaciers in 1925. By Jenny Visser-Hooft With contributions by Ph. C. Visser. Pp xii+303+25 plates. (London. Edward Arnold and Co, 1926) 21s net.

Kara-Korum is the name of a pass, yet it has been applied not only to the range containing the pass, but also to a tangled mass of mountains lying far to the west Exploration of this tangle has indicated that it consists of a series of ranges; so that the name Kara-Korum, as it is generally used, indicates a large district, rather than any particular range of mountains.

The area explored by Mr. and Mrs. Visser was limited to the headwaters of the Hunza River. The only way into most of the valleys lay through narrow gorges, occupied by rivers which were subject to sudden floods; so that the line of retreat was often closed for long periods. The party were actually imprisoned in this way in the Khunjirab valley, and were only saved from starvation by forcing their way over unknown glaciers and passes into the Shingshal valley. The glaciers in these valleys are unusually treacherous owing to the rapid melting of the ice under the tropical sun. Snow avalanches are common, but the greatest danger is caused by avalanches of stones. One such avalanche in the Hispar valley lasted

ducing the effect of a thick London fog.

The party successfully explored some of the largest glaciers in the world; the Batura glacier—37 miles of ice—and the chief glaciers in the Khunjirab and Shingshal valleys. The area traversed was mapped by Afraz. Gul Khan Sahib, whose services were lent by the Survey of India. Mrs Visser, who makes little of her own exploits, crossed glaciers and passes the existence of which was unknown even to the natives of the district. Two Swiss guides accompanied the explorers, and to their expert knowledge of ice, and its habits, the expedition probably owed its escape from the hourly dangers due to floods and avalanches

for many hours, and filled the air with dust, pro-

This book is illustrated by some excellent photographs.

The Scientific Feeding of Animals. By Prof. O Kellner. Authorised translation by Dr. William Goodwin. Second edition, revised Pp xiii +328 (London. Gerald Duckworth and Co., Ltd., 1926) 8s. 6d. net.

THE name of Kellner figures pre-emmently in the annals of the science of animal nutrition. Towards the end of the last century, at a time when little or no attention was being devoted in Great Britain to the elucidation of the scientific principles underlying the economic feeding of farm animals, Kellner was carrying out in Germany a series of classical researches which had the ultimate effect of raising the art of feeding to the level of a science. Indeed, the rapid progress which has been made in Great Britain during the last three decades in the development and application of the principles of feeding is, in large measure, a tribute to the excellence of Kellner's pioneer work.

Many students of animal nutrition science have had reason to feel grateful to Dr. Goodwin for the enthusiasm and initiative which led him, during the early years of the present century, to undertake the translation of Kellner's smaller text-book, Grundzuge der Futterungslehre" For many years this work stood unrivalled as a source of information to student, investigator, and farmer The welcome appearance of a new English edition has afforded Dr. Goodwin the opportunity of including the additional matter contained in the latest German edition, which has been revised and brought up-to-date by Prof. Fingerling, who succeeded Kellner at Mockern In particular, a new chapter on vitamins has been added. Despite these alterations, however, the book still remains, to quote Prof. Fingerling, "a masterpiece of H. E. WOODMAN. clearness and precision."

True Irish Ghost Stories. Compiled by Dr. St. John D. Seymour and Harry L. Neligan. Second edition, enlarged. Pp lxvii + 299. (Dublin: Hodges, Figgis and Co., London: Oxford University Press, 1926.) 7s. 6d. net.

The original collection of true Irish ghost stories appeared in 1914, and elicited a large number of additional examples which warranted a second and enlarged edition; but publication was delayed owing to the War. The re-issue is justified by the additions. The collection covers a wide range of phenomena. The three chapters which are devoted to haunted houses include some remarkable experiences, many of which are off the familiar track. One quoted from the Occult Review describes the apparition of what was clearly an elemental with characteristic hairless face and unpleasant stench. The poltergeist stories, as compared with some which have appeared recently in the Press in England, are, on the whole, disappointing as psychic manifestations, and indeed, except in the cases recorded by the late Sir W. Barrett, resemble folk-tales relating to these appearances rather than genuine experiences. Of the ancestral ghosts, some are already familiar to students of folklore, among them being the Gormanstown foxes, real foxes which on one occasion appeared

in Dublin itself There are several cases of invisible ghosts One, if invisible, was ponderable, for when it jumped on the handle bar of a bicycle the rider was compelled to pedal down a steep hill. Of apparitions before, at, and after death, and of the banshee, there are, as might be expected, numerous examples. The compilers present the stories without comment, and of course do not guarantee their genuineness.

Biological Relations of Optically Isomeric Substances By Prof. Arthur R Cushny (The Johns Hopkins University School of Medicine, the Charles E. Dohme Memorial Lectures, Third Course, 1925) Pp. vni+80 (London: Bailhère, Tindall and Cox, 1926.) 9s net.

In this short monograph the late Prof. Cushny has given an account of the pharmacological behaviour of those drugs which exist in an optically isomeric form. Starting from Pasteur's work on the separation of the two forms of tartanc acid by means of the differences in their crystalline form, the author describes how optical isomers can be separated by combining them with another substance which is itself optically active or by means of physical agents, such as heat, which in certain cases lead to the development of different properties by the two isomers. The relation of enzymes to optical isomers and the fate of the latter in the living tissues are then dealt with. Following a section on their pharmacological action, to our knowledge of which the author himself contributed by his researches, the final and most interesting chapter is devoted to some general aspects of this It appears probable that the specific activity of a drug depends on three factors. the general structure of the molecule, some special grouping, such as the alcoholic OH in the side chain of the acid in hyoscyamine, and, finally the presence of an asymmetric carbon atom. It is the latter which leads to a chemical combination between the drug and the cell, but it is on the second property that its specific action chiefly depends.

The Life of Buddha as Legend and History By Dr. Edward J. Thomas. (The History of Civilisation Series.) Pp. xxiv+297+4 plates. (London: Kegan Paul and Co., Ltd.; New York: Alfred A. Knopf, 1927.) 12s. 6d. net.

Dr. Thomas makes a first-hand contribution to the subject, based on a wealth of new material; while at the same time he gives to the layman a fascinating biography of a personality mysterious and real, and, to the philosophic mind, perhaps the most attractive among all religious reformers. The account of Buddha's life in the first chapters provides perhaps the most interesting reading—as a story. The discussion of our literary sources of Buddhism in the introduction, and the analysis of the text in the appendix, allow the specialist and the scholar from the neighbouring fields of history and sociology to obtain a real glimpse into the foundations of our knowledge of Buddhism.

Most interesting and valuable, however, are the chapters discussing Buddhism as a religion and a

philosophy, in its kernel of history, and in its aura of myth. The last chapter, containing a comparison between Buddhism and Christianity, shows how, in the light of modern scholarship, most 'parallels' and 'borrowings' vanish. While Seydel found fifty parallels, van den Bergh was reduced to nine, E. V. Hopkins to five, Garbe to four, Charpentier to only one, and "other scholars reject all connexion." The dogma of diffusion which has become of late so fashionable in anthropology, tends to disappear from history, that is, from the discipline which has full means of proving or disproving diffusion

Recent Advances in Biochemistry. By John Pryde. Pp. viii + 348. (London · J and A Churchill, 1926) 12s 6d. net.

This excellent little book, a companion volume of "Recent Advances in Physiology," which we have already noticed in these columns, gives an up-todate account of our knowledge on certain selected biochemical problems It should be useful both to the advanced student and to the worker who wishes to keep abreast of his own subject in branches with which he may not be directly familiar, without the necessity of referring to the original work Apart from chapters on the biochemistry of the proteins, fats, and carbohydrates, interesting accounts are given of the biochemistry of phosphorus and sulphur compounds, of the vitamins, and of hæmoglobin and related pigments in each case the latest work, at the time of writing, has been included. The author has purposely omitted any account of the mechanisms of tissue oxidations and the chemistry of the internal secretions, since both have been dealt with in the companion volume. instead, he has included two extremely useful chapters on the chemical basis of specific immunological reactions and on chemotherapy, subjects which are not often included in text-books of biochemistry: they are, however, among the most interesting of those dealt with in this volume. We can confidently recommend this book to all those interested in this subject.

An Introductory Course of Mathematical Analysis. By Charles Walmsley. Pp x +293. (Cambridge: At the University Press, 1926) 15s. net.

Dr. Young in his preface to this book explains that it was written to meet the needs of first-year students at Aberystwyth, many of whom arrived entirely ignorant of trigonometry, while others were proposing to take mathematical honours. Only the university authorities can judge of the success with which this staggering problem has been solved, but Mr. Walmsley has evidently been more concerned with the latter class than with the former, and his work will probably be useful chiefly as an introduction to Hardy's "Pure Mathematics."

So far as it goes, the treatment is thorough and sound. special attention is paid to inequalities and inequations, and a good feature is the proof of the addition theorems for the trigonometrical functions defined by their series

### Atmospheric Ozone and Solar Variability.

It has been known for a long time that variations in the annual mean values of the daily magnetic range were closely related to variations in the annual sunspot numbers. During recent months a number of other widely different terrestrial phenomena have been found correlated to some extent, at least, with solar changes and with each other.

Dr C G. Abbot has found that the monthly mean values of solar radiation show variations of the same character as do the monthly and annual sunspot numbers (US Monthly Weather Review, vol. 54. No. 5, May 1926). Mr. Greenleaf Pickard showed that there was a marked correlation between variations in sunspot numbers and radio reception at Newton, Massachusetts, and at Washington, D C. The companisons were made with wave-lengths of

8-9 megacycles. 15-25 kilocycles, and 1330 kilocycles. The measurements of the 8-9 megacycles and 1330 kilocycles were made at night, and those of the 15-25 kilocycles were made during daylight (Institute of Radio-Engineers, session of Jan. 10, 1927). Dr. L. W. Austin, of the U.S. Bureau of Standards, has shown that there is a strong correlation between the monthly means of radio receptivity and the monthly means of the Smithsonian measurements of solar radiation, and Dr. C. G. Abbot has found a marked relation between the total solar radiation and the ultra-violet radiation as measured by Dr. Pettit of the Mount Wilson Observatory. However, the variation in ultra-violet radiation is much larger, showing a range of about 60 per cent., while the total radiation shows a range of less than 5 per cent. (Smithsonian Miscellaneous Collections, vol. 80, No. 2, April 1927).

During the past two years Dr G. M. B. Dobson, Dr. D N. Harrison, and A. Lawrence, S.J., have made measurements of the amount of ozone in the earth's atmosphere at Oxford (*Proc. Roy. Soc.*, A, vol. 114; 1927). The monthly means of these values show an inverse relation to the monthly means of solar radiation as measured by the Smithsonian Institution and also to Dr. Wolfer's sunspot numbers. In the accompanying plot (Fig. 1) the continuous line shows the variations in the monthly means of ozone at Oxford, the broken curve shows the variations in solar radiation, and the dotted curve shows the variations in the monthly sunspot numbers.

The following table gives the departures of these three elements from the means of 19 months, using all the data available from Oxford The mean values are, for ozone, 0 284 cm of pure gas, sunspots 52, solar radiation, 1.940 gm cal per sq cm. per sec.

DEPARTURES FROM MEANS OF 19 MONTHS.

1925				1926			
	Ozone 1	Sun- spots	Solar Rad <sup>2</sup>		Ozone 1	Sun- spots	Solar Rad <sup>2</sup>
Feb Mar April May June July Aug Sept Oct Nov	+56 +20 +56 +37 +12 +15 -11 -18 -45 -37	$\begin{array}{c} -29 \\ -34 \\ -20 \\ -9 \\ -4 \\ -13 \\ -14 \\ +8 \\ +17 \\ +7 \end{array}$	$ \begin{array}{c} -4 \\ -9 \\ -7 \\ +3 \\ +4 \\ +5 \\ +8 \\ +8 \end{array} $	Feb Mar April May June July Aug Sept Oct Nov	$ \begin{array}{r} -6 \\ +6 \\ +5 \\ +20 \\ +17 \\ -18 \\ -26 \\ -56 \\ -52 \end{array} $	+17 +12 -13 +12 +20 -4 +11 +9 +26	$ \begin{array}{c} -1 \\ +1 \\ -7 \\ -6 \\ -3 \\ 0 \\ +2 \\ +2 \\ -2 \end{array} $

<sup>1</sup> Unit 0 001 cm

<sup>2</sup> Unit 0 001 gm. cal

From these numbers the correlation coefficient for ozone and sunspot numbers comes out,  $r = -0.62 \pm 0.09$ , and for ozone and solar radiation,  $r = -0.54 \pm 0.11$ . Presumably the correlation would be even higher with Dr Pettit's measurements of ultra-violet solar radiation, but the figures of his measurements are not at hand.

Dr Dobson and his associates believe that there is an annual period shown by the ozone measurements, and there probably is such a period, but its value cannot be determined from the data at hand; because while the ozone values decreased from about April to October in both years, it happens that the sunspot numbers and also the solar radiation values (both those of Abbot and Petint) increased from April to October in each year, and as there is an apparent negative correlation between these values and ozone at Oxford, it will take a number of years of observation to determine the terrestrial influence.

When the variations shown by the monthly means are eliminated and the day-to-day residuals are compared with sunspots, the relation between them is not evident. In 1925 the correlation coefficient was negative and in 1926 it was positive. But this result is not surprising. Dr. L. A. Bauer and C. R. Duvall found that the same thing was true of terrestrial magnetic variations (Terrestrial Magnetism and Atmospheric Electricity, Dec. 1925). The relation of these day-to-day magnetic variations to solar changes is different from that of the monthly means and its laws remain yet to be determined. In the case of solar radiation, the short period changes are connected in some way with the passage of spots with their accompanying clouds of calcium across the central part of the sun's disc, as I pointed out in Nature of Jan. 13, 1921, p. 630.

Dr. Dobson and his associates have shown that there is a very close relation between the day-to-day variations of ozone and the variations in pressure and temperature, more especially in the upper air. If future observations shall confirm the relation between the ozone values and variations in terrestrial magnetism and relate these to solar changes, they may furnish the key as to how solar radiation changes influence our atmosphere. Dr. Dobson has now established a network of stations for observing ozone, the preliminary results of which appear to show that there is an increase in the quantity of ozone and its variability from the tropics towards the pole. Since the ozone is found chiefly in the stratosphere, it may be that the increase of ozone with increase of latitude is associated with the increase in the depth

of the stratosphere which is found with increasing The increased depth of the stratosphere over areas of low pressure may also explain the increase of ozone with decrease of piessure in high latitudes

### The Mechanism of the so-called 'Posterior Sucker' of a Simulium Larva.

IN NATURE of April 23, p. 599, there appears a letter from Dr. Sunder Lal Hora of the Indian Museum, Calcutta, on the subject of the mechanism of the so-called 'posterior sucker' of the Simulium larva, in which he describes the true method of progression of this remarkable larva. In the course of his remarks, Dr. Hora quotes a passage from Tonnoir (Ann Biol Lacustre, 11, pp 163-172; 1923) to the effect that this worker, "not finding any muscles inserted in the middle of the disc, doubted its utility as a true sucker and ascribed the function of attachment to the hooks alone" He then goes on to discuss Dr Puri's well-known paper (Parasitology, 17,

pp. 295-369, 1925). Mr. Tonnoir worked at the life-histories of New Zealand Simuludæ during part of his two years' tenure of a research studentship at this institute, 1921-23, and the paper mentioned above contains some of his observations on the biology of Simulium larvæ. Apparently Dr. Hora has not understood the paper, but only made use of the last sentence in Section I., p. 165, as quoted by Dr. Puri, which is the least important of all Mr. Tonnoir's observations. The whole section, pp. 163-165, entitled "Progression et fixation des larves," deals very fully with the points raised in Dr. Hora's letter, and reaches exactly the same conclusions as he does, only they are given in more abundant detail and as the result of longer and closer studies of the larvæ in specially constructed running-water aquaria designed by Mr. Tonnoir himself

May I be allowed to quote, side by side, the two

sets of observations as briefly as possible:
(1) Tonnoir: "Les larves ne sont pas munies de rentouses, . . . il faut définitivement abandonner cette

théorie des ventouses tant postérieures qu'antérieures."

Hora. "the posterior appendage does not act as a sucker, but fixes itself with the help of hooks

(2) Tonnoir: "La larve fixe toujours, sans exception, l'extrémité postérieure de son corps exactement à l'endroit où se trouvait sa tête un instant auparavant, et, pendant le court instant où elle forme la boucle avec son corps, sa couronne de crochets postérieure (la soi-disant ventouse) vient toujours en contact avec sa bouche," "La larve dépose, avec sa bouche, une certaine quantité de matière glutineuse (dont elle forme ordinairement ses fils de soie) sur ces crochets postérieurs et sur le support; ainsi fixée solidement par l'extrémité postérieure, elle redresse ensuite son corps et l'étend. de toute sa longueur, en avant, pour se fixer au support par la bouche contre laquelle se trouvent appliqués les crochets terminaux de la fausse patte antérieure; elle ramène alors en avant en se pliant en U, son extrémité postérieure

et la série des mouvements se répète."

Hora: "These [the sucker-hooks] are capable of gripping firmly a cluster of silk threads (the sticky salivary secretion) which the animal secretes on the spot where it intends the posterior appendage to be fixed."

The only differences between the two accounts are

that Dr Hora supplements the lack of detail in his account by giving a figure of the tracks of the sticky secretion made by the larva, whereas Tonnour's detailed account makes a figure unnecessary.

The real difference in interpretation lies in the question of the muscles of the so-called 'posterior sucker.' In the larvæ of Blepharoceridæ, where true suckers are present, the muscles are of great strength, much stronger than the ordinary segmental muscles; this requirement is obvious, when one reflects that the vacuum is produced within the suction area by the long-continued contraction of these same muscles. The muscles of the 'posterior sucker' in Simulium larvæ, on the other hand, are much weaker than the segmental muscles, as Dr Puri's figure (pl vui. fig 10) clearly shows, and could not possibly accomplish this Tonnoir had the blepharocerid larva in function mind (on which he was also working at the time) when he wrote "il n'existe pas de faisceaux musculaires destinés à la formation de cette coupe"; he did not imply that no muscles existed, but only that no muscles strong enough existed. To call these muscles 'strong,' as Dr Hora does, seems to me misleading; they are strong enough to pull the disc from the sticky secretion, but, compared with the segmental muscles, and more especially with the sucker muscles of Blepharoceride, they should be described as 'weak'

The principal object of this letter is to show that Dr. Hora, by not carefully reading Mr Tonnoir's paper published four years earlier, has laid claim to a discovery which has been even more fully made and more beautifully described by a brilliant worker in this Institute R. J. TILLYARD

Biological Department, Cawthron Institute, Nelson, N.Z., May 31.

### Radiation of Stars and Thermodynamical Fluctuations.

ACCORDING to modern views the substance of the sun and stars is in a state closely approximating to that of a perfect gas. These spherical gaseous bodies have been extensively studied on the basis of classical thermodynamics. It can scarcely be doubted that the internal layers of a star are in an almost perfect thermodynamical equilibrium having a radiative character, as has been convincingly established by Eddington.

It is only in the close proximity of the surface that considerable deviations from this state of equilibrium can occur.

In this note I wish to suggest that the theory of the stars may be greatly enlarged and improved by an introduction of a new agent, namely, thermodynamical fluctuations.

It is shown in statistical mechanics that the thermodynamical equilibrium is never absolute, there are always fluctuations, namely, irregular oscillations about a state of equilibrium.

When the system under examination is closed this state undergoes no change in the course of time. But a star must be regarded as an open system, which can exchange energy with surrounding bodies. In such a system the exact balance of fluctuations cannot exist either on the surface or in the deep interior. In these conditions the external radiation will appear as a necessary consequence of fluctuations.

The thermodynamical fluctuations may be of different kinds. The most important for our purpose are the fluctuations of emission and absorption. If E is the energy of full radiation contained in a volume

V, of frequencies corresponding to the interval  $\nu$ ,  $\nu+d\nu$ ;  $E_0$ , its mean value;  $\epsilon=E-E_0$ ;  $\overline{\epsilon}^2$ , the mean value of  $\epsilon^2$ ; h, Planck's constant, c, velocity of light, then

$$\overline{\epsilon^2} = h \nu E_0 + \frac{c^3}{8\pi \nu^2 d\nu} \frac{{E_0}^2}{V}.$$

The first term on the right side of this equation depends on the fluctuation of emission and absorption; the second term originates from the interference of rays crossing the volume V in all directions. Denoting the first part of  $\epsilon^{2}$  by  $\epsilon_{1}^{2}$  we have

$$\sqrt{\tilde{\epsilon_1}^2} = \sqrt{h\nu E_0}. \qquad . \qquad . \qquad . \qquad (1)$$

In what follows we shall apply this formula to the total radiation contained in a volume V, understanding by  $\nu$  a mean frequency. In certain elements of a star the quanta  $h\nu$  of energy are produced in an excessive number: in the other, it is the inverse process of absorption which predominates. The compensation of these two opposite processes is not complete with regard to the external radiation of the star Imagine the centres of increased emission and absorption irregularly disseminated throughout the total volume of the star; a part of the excessively emitted radiation gets free of the star into interstellar space. This is, I think, the mechanism of the external radiation of stars.

The exact computation of the resultant effect arising from fluctuations of emission and absorption in innumerable elements of a star seems to be a very difficult task. Much easier may be an approximate comparison of stars with respect to their external radiation considered as a shining due to fluctuations.

Let us admit that this radiation per unit volume is proportional to  $\sqrt{\epsilon_1^2}$ . In the formula (1)  $E_0$  is proportional to  $T^4$ ,  $\nu$  may be assumed proportional to T (absolute temperature), therefore, denoting by  $\sigma$  the energy externally radiated per unit mass of a star, we have

$$\sigma = \alpha \rho^{-1} T^{\frac{5}{2}}, \qquad . \qquad . \qquad . \qquad (2)$$

where  $\rho$  is the mean density, a a constant coefficient This law of radiation is no more than a rough approximation , nevertheless, it explains in a striking manner the diversity of the outflow of radiation per unit mass from different stars

Let us in the first instance compare the sun with Capella (the brighter component). The data necessary for us derived from astronomical observations are as follows:  $\sigma_{\text{Capella}} = 58$ ,  $\sigma_{\text{Sun}} = 1.9$ , whence  $\frac{\sigma_{\text{C}}}{\sigma_{\text{S}}} = 30.5$ ;

the density of the sun is 620 times that of Capella, the temperature is 43 times higher in the sun at corresponding points.

Eddington considers as a natural supposition that  $\sigma$  must be proportional to the density and to some higher than first power of temperature, say, second power. It follows that the quotient  $\sigma_{\rm C}/\sigma_{\rm S}$  should be about  $170\,070$ .

We have here, as Eddington points out, an "awkward paradox" (see "The Internal Constitu-

tion of the Stars," p. 397) Our formula (2) gives an explanation of the fact that with a smaller density is associated greater external radiative power; for the quotient  $\sigma_{\rm C}/\sigma_{\rm S}$  we obtain 16·2 instead of 30 5: the better agreement

might not be expected. We may also compare the sun with the variable star  $\delta$  Cephei. We have  $\frac{\sigma \delta_{\text{Cephei}}}{\sigma_{\text{Sun}}} = 55$ ; the density of the sun is 4120 times that of  $\delta$  Cephei, the tempera-

ture of the sun is 6 6 times higher. From formula (2) we obtain  $\frac{\sigma_{\delta C}}{\sigma_S} = 37$ . Thus the confrontation of theory and observational data provides a serious argument supporting the view that the external radiation of stars is a consequence of thermodynamical fluctuations

Further consideration of this subject will be found in a communication presented to the Polish Academy of Sciences on June 10, 1927.

Tcheslas Bialobjeski.

Warsaw, June 20.

## The Transition from Ordinary Dispersion into Compton Effect.

The dispersion formula of Kramers and Heisenberg is valid for an atomic system the dimensions of which are small compared with the wave-length of incident light. For very short waves the scattering from an atom will of course approach the Compton effect for free electrons; and this has been treated very fully by Dirac and Gordon. A treatment of dispersion theory on the basis of wave mechanics has been given by Schrodinger and Klein, who have also outlined a simple treatment of the Compton effect. Following a procedure rather analogous to that of Klein, it is possible to work out a generalised dispersion formula, holding also for waves short compared with atomic dimensions and making it possible to follow the gradual transformation of ordinary dispersion into the Compton effect.

For elements of low atomic number this transformation can be followed through various stages. The following brief account relates to an atom containing only one electron. During the first stage, while the wave-length of the radiation remains throughout long compared with atomic dimensions, its frequency varies from being of the same order as the characteristic frequencies of the atom to values large in comparison with these frequencies. The characteristic dispersion gradually transforms into the scattering, which must be expected on ordinary electrodynamics for free electrons, and which is given by the well-known formula of J J. Thomson. This formula holds approximately down to wavelengths approaching atomic dimensions. At that stage the scattering of coherent radiation will begin to diminish and will gradually be more and more concentrated in the direction of the incident light. Simultaneously with this effect, an incoherent radiation of frequencies equal to the difference between the incident frequency and the characteristic absorption frequencies of the atom will appear.

At first the intensity of this radiation will be mainly distributed over a few frequencies, the light of each component being scattered in all directions. As the wave-length decreases, the distribution of intensities amongst the various components of the scattered radiation will become more and more nearly a distribution which gives the well-known relationship between direction and frequency for the Compton effect, and also the intensity formula of Breit and Dirac. The phenomenon will have practically merged into the Compton effect when the momentum of a quantum of the incident light is large compared with the mean value of the momentum corresponding to the electronic motion in the atom. It is of interest to note that even at this stage the Thomson formula holds with a close approximation for the total intensity of the scattered light in any direction. This formula first ceases to hold approximately when the frequency displacement of the Compton effect is no longer small compared to the frequency of the incident light.

The mathematical discussion of the problem in question makes use of the fact that in the region where the frequency of the light is large compared with the natural frequencies of the atom, it is possible to calculate the scattering with high approximation directly from a knowledge of the wave functions of the undisturbed atom, the calculation being in this respect simpler than that of ordinary dispersion theory. It may be noted that the coherent part of the radiation is in this case directly calculated from that continuous distribution of electricity which is defined by Schrodinger's density distribution in the initial state of the atom.

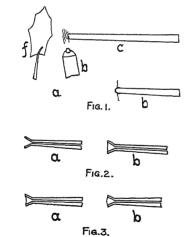

I wish to express my thanks to Prof. N. Bohr, Prof. C. G. Darwin, and Dr. O. Klein for their valuable interest in this work, of which a fuller account will be published shortly.

IVAR WALLER.

Copenhagen, Universitetets Institut for teoretisk Fysik, June 1.

#### The Mounting of Thin Glass Windows.

RECENTLY (early spring of 1926) it became desirable to produce a source of a-rays free from the disturbing effects of the accompanying emanation. This source was to be used in connexion with a simple a-ray track apparatus designed by the writer (Jour. Optical Society of Amer., vol. 11, No. 2, Aug. 1925; Science, vol. 64, No. 1649, Aug. 6, 1926). The solution came from a suggestion by one of the writer's students, L. P. Garner, a graduate in electrical engineering, University of Illinois, and for the above purpose leaves nothing to be desired Briefly it is as follows. A cane c (Fig. 1) of solid glass (Pyrex or Monax) is broken off squarely. On the centre of this end is placed a

minute film of dilute shellac, which serves to hold a microscopic quantity of radioactive salt (radium bromide was used). Now prepare a film f by blowing it out of the same glass and so thin that it will show Newton's rings. Hold this film with a pair of forceps in front of and distant about  $\frac{3}{4}$  inch from the tip of the cane bearing the radioactive salt and bring them up to a soft blast b, as shown in Fig. 1, a. Heat carefully, and as soon as the square tip begins to assume a globular form thrust it through the film f. The result is a varnish of glass, as it were, enveloping the front side of the globule as shown in Fig. 1, b. The burr is now brushed off and the emanationless source of a-rays is ready for use, providing no mishap was encountered.

A step further in the process is the fusing on of glass windows This has been carried out during the past few months at the Cavendish Laboratory. Figs. 2 and 3 show the essential steps The cavity on which the window is to be fused should be prepared with care, the lip should be square and symmetrical, and the glass walls should be rather heavy. Best results will be secured by the beginner if the opening of the cavity to be glazed be not more than 2 mm. inside diameter. The capillary leading to the cavity may have, of course, any dimension desired. If a plane window is desired the capillary must not be obstructed during the operation. The procedure is the same as for the solid cane. Care must be taken not to overheat the edge of the cavity or else it may become deformed; also this hot edge when thrust through the film f must strike it squarely—an operation that succeeds after several trials. Windows of 005 mm thickness and 2 mm diameter will withstand a vacuum either in or out.

A much thinner film of glass may be used for a given diameter of window if it is fused on concave or convex, as shown in Fig. 3, a and b. The process after all is very simple. To produce a concave window attach the capillary cane to an aspirator stopped down to produce an exceedingly small suction, and proceed as above. The amount of concavity produced is readily regulated by adjusting the suction. Again, to form a convex window it is only necessary to close the capillary with a little soft wax while fusing it on. The expanding air within will give it the desired convexity. A few trials may be necessary. When successfully done these fused junctions are vacuum tight and present a beautiful appearance under a magnifying glass.

Windows thus fused on should prove useful in a

number of researches with a-rays.

CHAS. T. KNIPP.

Cavendish Laboratory, Cambridge, June 30.

#### Modern Photometry.

I WISH to clarify a somewhat confused account of some work of mine given in Walsh's "Photometry," pp 244-245 (London: Constable, 1926). Since the same mistake has also been made by others heretofore and bids fair to become prevalent, it seems desirable to publish a correction. I do this not for the sake of finding fault, but to prevent, in so far as possible, the continued spread of mistaken ideas in regard to the subject matter in question. It is well known how errors once incorporated in a standard text are copied and re-copied without limit.

The error in question is that the instrument designated by Dr. Walsh as "The Leucoscope" is not the leucoscope, but the "rotatory dispersion colorimetric photometer." The pertinent facts are as follows:

(1) The leucoscope is an instrument the invention of which is commonly attributed to Helmholtz, about 1870–80. There has been some slight controversy as to the relative contributions of Helmholtz, and one of his pupils, Diro Kitao, to its development Edm. Rose (1863) described an instrument which may be regarded as the prototype of the leucoscope A review of the history of the instrument and a full bibliography have been published in my paper on the leucoscope (Jour. Op. Soc Am., 4, 448-495; 1920). It consists essentially of a quartz plate between a Wollaston prism and a nicol prism through which the observer views two images of the same source.

(2) The instrument which Dr. Walsh describes and calls "The Leucoscope" is properly called the "rotatory dispersion colorimetric photometer" (J.O.S.A.

and R.S.I. 7, folded insert facing p. 1199; Dec. 1923). I particularly object to naming it "Priest's leucoscope" as is done in the index of Dr Walsh's book. It is a special form of the Arons' chromoscope (Leo Arons: Ann. der Phy (4), 39, 545-568; 1912), and its embryonic form may be seen in Zoellner's colorimeter (J C F. Zoellner: "Photometrie des Himmels," Berlin. 1861 G. Mueller: "Photometrie der Gestirne," pp 244-254; Leipzig, 1897) My connexion with this instrument has been to develop the theory and practice of its use in the colorimetry and photometry of incandescent sources and daylight, and to design an instrument especially suited to these purposes.

(3) In principle, manner of use, and specific purpose served, the two instruments are very different. About all that they have in common is the fact that they both contain nicol prisms and quartz plates and the circumstance that I have written papers dealing with

each of them separately.

It seems unnecessary to occupy space by setting forth in detail the distinctions between these two instruments. All confusion may be removed by consulting my papers which deal respectively with the two different instruments, namely, "A New Study of the Leucoscope..." (J O.S.A., 4, pp. 448-495; Nov. 1920), and "Colorimetry and Photometry... by the Method of Rotatory Dispersion" (J O.S.A. and R.S.I., 7, pp. 1175-1209; Dec. 1923).

IRWIN G. PRIEST.

Department of Commerce, Bureau of Standards, Washington, June 21.

Mr. IRWIN G. PRIEST has been good enough to send me a copy of the above letter concerning the description, in my recent book "Photometry," of the instrument developed by him for heterochromatic

photometry (pp. 244-5).

While agreeing, of course, that his instrument is m no wise identical, either in principle or in use, with Helmholtz's 'Leucoscope,' it still appears to me that 'Leucoscope Photometer' is a not inappropriate description of the instrument, which is, in essence, a photometer in which a colour match is obtained by means of the rotatory dispersion of quartz, and a brightness match by means of polarisation prisms. Nevertheless, it is clear that as Mr. Priest is the inventor of the instrument, he must necessarily be entitled to object to having any name attached to it which, in his opinion, is liable to lead to misunderstanding. I can therefore assure him that should a further edition of my book be called for, the alteration will certainly be made. In the meantime I feel sure Mr. Priest will agree that the description of the instrument which I have given in the text of my book is in no way misleading.

## The Dissociation of Carbon Dioxide at High Temperatures.

WHEN mixtures of carbon monoxide and air in varying proportions are exploded in a closed vessel under similar initial conditions of pressure, temperature, and moisture content, experiments show that the greatest explosion pressure occurs when the proportion of carbon monoxide to oxygen in the mixtures is greater than 2. Messrs. Fenning and Tizard, in their paper on the dissociation of carbon dioxide at high

temperatures in a recent number of the *Proc. Roy. Soc.*, assume that chemical equilibrium is established by the time the maximum pressure is reached in explosions and attribute this phenomenon entirely to temperature dissociation of carbon dioxide. They then proceed to make estimates of the dissociation of carbon dioxide as a function of temperature from explosion experiments in which the 'airs' used were enriched with oxygen so as to develop higher temperatures.

157

The assumption that chemical equilibrium is attained at the maximum pressure in explosions is, I believe, erroneous and dissociation values calculated from explosion experiments upon this basis

are much too high.

Some earlier experiments of mine in which measurements of heat loss were made during explosion convinced me that chemical equilibrium is not attained at maximum pressure—at any rate in explosions of complex mixtures like those of coal-gas and air. Recently we have been working in Leeds with pure gases (carbon monoxide and hydrogen) and have come to the conclusion that even with such gases chemical equilibrium is far from being attained at maximum pressure. One of the methods employed is, on the experimental side, precisely similar to that adopted by Messrs. Fenning and Tizard, but the range of our experiments is wider in that we have made investigations at explosion temperatures so low that dissociation is insignificant as well as at higher temperatures. Thus Mr. R. A. Smith, a research student, has experimented with carbon monoxide explosions, varying his 'airs' so as to investigate the temperature range 1600° C. to 3000° C. His experiments prove that the amount of uncombined gas at the maximum pressure in 'complete combustion mixtures' is at least 10 per cent. of the original charge when the explosion temperatures are below about 2000° C., but as the explosion temperatures are increased the amount of uncombined gas increases. The explanation would appear to be that below 2000° C. the uncombined gas is due to incomplete combustion and that above 2000° C. dissociation adds to this. It seems clear, then, that the assumption of chemical equilibrium at maximum pressure is unjustifiable.

Mr. Smth's explosion vessel consists of a sphere 6 inches in diameter, and the gaseous mixtures before explosion were at atmospheric temperature and density. Our work suggests the desirability of experimenting with vessels of various sizes and shapes and also at various densities, and we propose to arrange for this before publishing our results in detail.

#### Polyploidy within a Species.

The importance of taking chromosome characters into consideration in the study of genetical problems is becoming increasingly more apparent, particularly in relation to the species problem, and any peculiarity in this respect requires careful attention. The study of large genera and of the occurrence of polyploidy within their limits, as exemplified by Rosa and other genera, has thrown considerable light on the origin and interrelationships of the various species. In investigating Silene and the neighbouring genera from this point of view, the actual base number of chromosomes is itself of considerable interest, since in Saponaria and Dianthus it may be 14 or 15, whereas in Silene, etc., it is invariably 12. So far, however it is these latter genera, Silene, Melandrium, Lychnis,

etc., which have chiefly occupied my attention, and it appeared, at first, as if the question of polyploidy scarcely arose at all; even now, after the investigation of more than sixty species, only seven have been found to be other than diploid. Among these, however, one, Silene ciliata, has shown itself of such exceptional interest that it seemed to me worth while directing special attention to it In the genus Silene, although more than thirty species have been examined, only two show polyploidy of these S vallesia is a normal tetraploid, whilst in the case of S ciliata I have investigated two races, one of which is tetraploid and the other has a haploid count of 96 and is therefore 16-ploid. The plants of this latter race were perfectly normal in chromosome behaviour and fertile. The two races were obtained from different sources and both were quite typical, and this within a species which is somewhat variable.

Although cases are known in which tetraploidy does not produce a 'gigas' form, it does seem somewhat surprising that a race can alise with four times the normal number of chromosomes, and with actually the largest but one recorded figure for angiosperms, and yet show no obvious difference in appearance.

That this is a case of continuous duplication of chromosomes rather than segmentation of the individual chromosomes is strongly suggested by the observation that the size of the chromosomes is little less in the case of the 16-ploid race; even the characteristic ring shape at the heterotype division is retained. The volume of the pollen mother-cell in the two forms is very little different, that of the tetraploid being about three-quarters that of the 16-ploid. The chief difference in cytological appearance is due to the extremely close packing of the chromosomes in the latter case.

This record seems to minimise the value which has frequently been attached to mere multiplication of chromosome sets and, at any rate within the limits of the Silenoideæ, to emphasise the importance of the original set characteristic of the genus

### Optical Behaviour of Protein Solutions.

A VERY remarkable increase in light-scattering power is exhibited by gelatine solutions when the hydrogen-ion concentration approaches the value (about pH = 5) corresponding to the iso-electric point. This effect, which appears to have been known for some time, has been recently studied in detail by Kraemer and his co-workers, who give interesting curves showing the manner in which the Tyndall effect varies with  $p{\bf H}$  and temperature ("Colloid Symposium Monograph," vol. 4, and Journal of Physical Chemistry, May 1927).

The phenomena are scarcely intelligible on the view commonly adopted that the Tyndall effect in a colloidal solution is simply proportional to the number of scattering particles of the same kind present in it. Their explanation becomes clearer if we apply to colloidal solutions the general thermodynamic theory of light scattering, in which the Tyndall effect is regarded as due to local fluctuations of optical density in the medium. According to the latter theory, the scattering power of a colloidal solution would be connected with the osmotic pressure P of the particles, by the relation

 $rac{\pi^2 RT}{2N\lambda^4} rac{k(\hat{c}\epsilon/\hat{c}k)^2
ho/m}{\hat{c}P/\hat{c}k}$ ,

where k is the concentration of the dispersed material,  $\epsilon$  is the optical dielectric constant of the solution and

 $\rho/m$  is practically unity for a dilute solution. It is well known from the work of Jacques Loeb that the osmotic pressure of a gelatine solution alters in a notable manner with pH, becoming very small at the iso-electric point. Equation (1) then enables us to see at once why the Tyndall effect becomes very large under the same conditions.

A detailed discussion of colloidal optics on the basis of the thermodynamic theory of light scattering will be published in the Indian Journal of Physics C. V. RAMAN.

### The Relationship between Chinese and Arabic Alchemy.

SINCE my communication on the subject of Chinese alchemy (NATURE, Jan. 1, 1927) was written, I have received the very important memoir entitled "Chemistry in Iraq and Persia in the Tenth Century a D.," by Principal Stapleton, the late Mr. Azo, and Mr. M H. Husam, published in the Memoirs of the Asiatic Society of Bengal, vol 8, No 6, 1927. In this (p 405) the treatise on Taoist alchemy, Pao p'o tsz of Ko-Hung (A D 330), to which I referred, is mentioned, and a summary of the alchemical contents of three of the 'Inner chapters' (Nuy peen), translated from an edition published in 1884, is given. This information does not go further than that already published, and it would seem that the account given by Edkins is nearly complete. The authors then remark (p. 406) that: "The above account is sufficient to prove (a) that Chinese alchemy was concerned almost entirely with Mineral Chemistry: and (b) that Ko-Hung's materials were so extraordinarily similar to those used by Arabic and Greek alchemists that it is certain that Chinese, Greek, and Arabic alchemy must have had a common source of origin " They also refer (p. 405) to a further possible source of Arabic alchemy, namely, the Chinese School of Alchemy which was flourishing at least as early as 200 B.C'

It will be seen that the distinguished Oriental scholar has reached the same conclusion as myself: the only difference between us appears to be that he regards Chinese alchemy of 200 B.c as well established, whilst I consider that this still awaits satisfactory demonstration. An examination of the information dealing with this earliest period by a competent expert is still necessary. J. R PARTINGTON.

Kingsbury Close, London, N.W.9.

#### Fictitious Amazons.

The efforts of syndicated journalism to popularise research occasionally lead to misunderstandings. I have to-day received a cutting from the Daily Mail of Bombay, dated June 14, devoting two columns to discussion of views about the ancient Amazons, which I am represented as having maintained at a meeting of the British Association for the Advancement of Science. Will you give me the opportunity of saying that neither before the British Association nor before any other public body have I discussed the ancient Amazons at all. Similar announcements have been appearing in French, Belgian, and especially in American, papers during the past six months, in connexion with the Philadelphia meeting of the American Association last December. It is true that I attended that meeting as the representative of the British Association, and gave a public lecture on some aspects of the geography of Greek lands; but that lecture contained no reference to the Amazons.

Will Indian, French, Belgian, and especially American newspapers 'please copy'?

JOHN L. MYRES.

### The Resources and Applications of Manganese.

UR very material and complex civilisation, admittedly only rendered possible by the developments in metallurgy, is indebted to the chemists of the eighteenth and early nineteenth centuries to an extent not always appreciated for their success in isolating the elements, and particularly the metals Their efforts were largely sustained by the desire for knowledge, since material reward in the modern sense could scarcely be contemplated, and, indeed, did not enter into the thoughts of many of these pioneer investigators. The world owes much to the Swedish chemist Gahn, who first successfully isolated the metal manganese in the latter half of the eighteenth century. As regards the application of the element in the metallurg of steel, the two outstanding names are Mushet and Hadfield Mushet discovered its value when added in small quantities in the manufacture of ordinary commercial steels, whilst Hadfield produced an alloy of iron and manganese having properties entirely new and unsuspected in the range of ferrous metallurgy. Hadfield's manganese steel led the way in the successful development of alloy steels This material, when quenched in water from a high temperature, becomes soft and tough, whereas previous steels became hardened by such treatment. By virtue of the discovery of such phenomena, investigators were led into a proper appreciation of the changes taking place in iron and steel with change in temperature Sir Robert Hadfield we are indebted for two extremely interesting papers presented at the May meeting of the Iron and Steel Institute reviewing the world's resources of manganese, the other containing the results of his latest researches on the iron-manganese-carbon system. It is of value that an investigator who over a long life of continuous research in a field which he has made peculiarly his own, should review the sub-

When it is remembered that manganese was only first isolated in 1774, the metallurgical achievement at the present time of smelting  $2\frac{1}{2}$  to 3 million tons of ore is indeed considerable. Such are, however, the advantages of the alloying of the metal with iron that it is indeed desirable to review the position, particularly in regard to the British metallurgical industries. In an interesting and valuable contribution to the discussion upon these particular papers, Sir Thomas Holland quite rightly asks whether, and to what extent, scientific and technical matters such as these should be confined in discussion to technical institutions, and whether the larger public should be instructed in the economic and political aspects of the matter. The discussion in which Sir Thomas took part undoubtedly gives the answer, since the extent of the resources and the distribution of the ores were brought home to a large audience, many of whom no doubt were instructed by the paper and the ensuing speeches. Particular attention might be directed to an excellent map given by Sir Robert Hadfield showing the known sources of manganese ore in relation to the British Empire, and whilst it is clear that we have excellent deposits within the Empire's borders, it is also clear that to retain the advantage of them, and to receive adequate supplies for the home industries, our sea routes must be kept open—India, the Gold Coast, Russia, and Brazil are indicated as the largest present sources of supply; large deposits not fully developed occur in South Africa, Europe, and South America, whilst there are few parts of the world where the ore is not worked—Cost, however, is vital, and the richest, more easily available, and the nearer the deposits, the better is it for the consuming industry

Turning to the commercial reduction of the metal from the ore, the survey of the development indicates rapid technical progress. The discovery of the influence of manganese in facilitating the production of good steel by Sir Henry Bessemer's process, naturally led to concentration upon the

matter of supplies of the metal

It is described how Heath in 1839 first made the application of manganese to steel production possible by the use of his carburet of manganese, but it should be remembered that at that date, and for some time afterwards, liquid steel could only be produced in small crucibles which men could lift. It was the advent of Bessemer's process, described by him in 1865, which made possible the engineers' dream of a mechanical world based on iron and steel Without manganese, the process was not practicable. Largely through the experiments of Mushet, who had been working at the production of metallic manganese from 1830 onwards, it was shown that the addition of manganese to Bessemer's blown metal produced a very tough workable steel, and ensured the commercial success of the process destined to revolutionise everything, since, for the first time, cheap steel in great quantities became possible for the multiplication of railways and ships, and a multitude of minor services upon which our civilisation is so dependent. By 1865, at the suggestion of Bessemer, Henderson in Glasgow was making an alloy of iron and manganese, containing 25 to 30 per cent. manganese, by his own process, which consisted of reducing, upon the hearth of a Siemens' furnace, 'a mixture of carbonate of manganese and oxide of iron in the presence of excess carbon by means of a neutral or reducing flame." M. Pourcel and his colleagues then developed in France the production of ironmanganese alloys, very rich in manganese, by blastfurnace methods, and such indeed was the progress during the years 1875 to 1885, that even during this period the alloy was available with more than 80 per cent. of manganese and produced at a price so low as to constitute an adequate complement to the economic side of Bessemer's process. Our British ironmasters were not slow to follow, and manganeseiron alloys of a wide range of composition became suitably available, both in quality and tonnage, to meet the needs of the rapid increase in steel production.

We now come to consider a most important phase

of the manganese production. Whether the alloy was ferro-manganese with a very high percentage of manganese, or 'Spiegel' containing low percentages of manganese, it necessarily contained a high percentage of carbon, owing to the fact that it was produced in the blast furnace with coke as the reducing agent. Manganese alloys were not available except with a high carbon content, and the carbon ranged at so high a value as 40 to 7.0 per cent. This was fortunate as regards the Bessemer process, since that process consisted, in Britain, of blowing air through liquid crude iron until finally only very small quantities of the carbon, manganese, and silicon remained, and therefore it was just as necessary to add carbon as manganese before finally casting the steel. Since the manganese addition of the order of 1.0 to 20 per cent. remained constant, and the carbon of steel must vary according to the purpose to which it was to be put, it will be seen that by choosing suitable ratios of manganese and carbon in the manganese alloy the desired result was obtained.

As an interesting departure from the normal Bessemer process, it should be recorded that the Swedes developed an indigenous modification based on the use of crude iron rich in manganese, and that at the end of the blowing period, sufficient of the element remained in the iron to make additions unnecessary. Some of us had the pleasure of seeing this process in operation last autumn through the courtesy of our Swedish friends, and it was interesting to see how the retention of manganese in the liquid bath permitted a technical control of the blowing operation, since the blowing could be arrested, the composition of the bath determined and blowing proceeded with intermittently until the desired carbon content was attained. considering the development of the early major steel processes, it should always be borne in mind that the physical chemistry of the reactions was even less completely mastered than at present, and that the whole of the development was necessarily accomplished by empirical methods. The achievements of the last century demand our appreciation.

Turning now to the discovery of manganese steel, Sir Robert Hadfield must have been a very young man when, in the early 'eighties of last century, the idea occurred to him of adding the manganese alloys then available in varying proportions to iron with the resultant production of a series of ironcarbon-manganese alloys, one of which proved to have astounding properties. It had previously been understood that if more than 2 or 3 per cent. of manganese was added to steel it became uselessly hard and brittle. Indeed, the whole of the experimental series produced by Sir Robert were very low in ductility in the as-cast condition, but his research was carried further, and by various experimental heat-treatments he discovered that in a range of composition, quenching in water from a high temperature produced alloys of great ductility, and other valuable characteristics. It will thus be seen that the discovery of manganese

steel did not simply result from the melting of the materials in different proportions, but necessitated, in addition, a well-conceived research covering subsequent treatment.

Manganese steel' is still produced to the original composition and treatment as determined as a result of the original researches It contains 13 to 14 per cent. of manganese, and between 1.0 and 1.5 per cent. of carbon. In the water-toughened condition it has a tensile strength of 60 to 70 tons per square inch, accompanied by a ductility indicated by an elongation of 40 to 60 per cent. Although very tough, its wear resistance is remarkable, and this property has led to its manufacture in very large quantities. Its great ductility, accompanied by its high strength, led to the production of many millions of soldiers' helmets during the War, whilst its non-magnetic properties have found applications in many, and in some extremely curious, directions. It should, however, be borne in mind that this steel is a ternary alloy, ie. it consists essentially of iron, manganese, and carbon, and, as Sir Robert points out in the second paper under consideration, his early discovery was facilitated by the high carbon content of the early manganese alloys, available at the time, resulting from their reduction in the blast furnace in the presence of an excess of carbon.

It always intrigued the minds of metallurgists as to what would be the properties of iron-manganese alloys of similar composition in the absence of carbon, but until comparatively recently it was only possible to approximate to the necessary experimental conditions, owing to the difficulty of obtaining 'carbonless' manganese. The efforts of many investigators have culminated in it now being possible to fulfil the conditions reasonably. Sir Robert Hadfield has been able to produce a series of iron-manganese alloys in which the manganese content varies from 1.68 to 83.5 per cent, with a carbon content not exceeding 0 20 per cent. until the manganese exceeds 390 per cent. Whilst not even yet quite fulfilling the desire to produce a series free from carbon, yet the carbon content is undoubtedly exceedingly low when it is borne in mind that sufficient of each alloy was produced to investigate the wide range of properties satisfactorily. It is instructive that Sir Robert was able to secure metallic manganese containing 99.52 per cent. of the element with only 0.11 per cent. of carbon. A survey of the results will show that comparison is now possible of the data to be obtained from a 13.0 per cent. manganese steel containing 0 09 per cent of carbon, with the standard product, which contains approximately fifteen times that amount, that is, 14 per cent. The experiments indicate the necessity of the high carbon content for the essential wear-resisting property; that the non-magnetic properties can be achieved with the low carbon, but by considerably increasing the manganese content; but that the high strength and great ductility are impracticable, except with a substantial carbon content. The paper contains much data of value to the specialist, and although space prevents the writer doing so, the author duly acknowledges the work of others in the same field with a thoroughness which is by no means invariably a noticeable feature in scientific papers.

Manganese has its applications in other branches of metallurgy, and its compounds have been applied

industrially down the centuries, but enough has been written concerning its value to the key iron and steel industries to emphasise the importance of ensuring that, whether we be at peace with the world or not, our supplies must not be interrupted.

W. H. H.

### Lister's Methods in Surgery.1

By Sir W. Watson Cheyne, Bart., K.C M G., C.B., F R S.

IT is curious how events and discoveries fit into their proper place in the history of the world, and how one discovery may often dovetail into another and increase the usefulness of both. I have in my mind the discovery of anæsthesia and

asepsis

Anæsthesia alone was naturally a very great gain to mankind both in saving pain and in reducing shock, but in some respects it was a disadvantage. Before its introduction, the hall-marks of a good surgeon were rapidity in operating and thorough anatomical knowledge. The range of operative work, however, was not very great. But the fact that pain could be abolished and shock considerably reduced by anæsthetics had the effect of encouraging surgeons to perform more prolonged and intricate operations. The consequence was that, as sepsis was as frequent and as dangerous as before, this meant an increase in the number of cases of sepsis and in the mortality in the surgical wards, and surgeons became more doubtful than ever of the advisability of extending the area of surgery.

As soon, however, as Lister had firmly established his aseptic methods, this difficulty passed away; rapid and enormous extensions of the limits of surgery were introduced by him and his followers, and anæsthesia took a permanent and most im-

portant place in forwarding this

The times were indeed ripe for the revolution made by Lister in the treatment of wounds. For ages, those who practised surgery were constantly confronted by the various septic diseases following wounds, whether made accidentally or by the surgeon. Occasionally, some one had a glimpse of the truth, but the wound treatment, whatever its nature was, had as its object the application of dressings and medicaments in order to make the flesh heal, as opposed to Lister's principle of leaving the wound itself alone while striving to remove all agencies which might hinder the wound from healing.

The cause of the septic troubles was for long looked on as connected with the admission of air to the wounds, and when oxygen was discovered, that gas was generally blamed for setting up changes in the blood and tissues. But towards the end of the eighteenth century, John Hunter pointed out that it could not be the gases in the air which caused harm, for in cases of emphysema and pneumothorax due to fracture of a rib and puncture of the lung, the tissues and the pleural cavity became distended with air; but neither sepsis nor suppuration supervened. Therefore Hunter was in favour

 $^{\rm 1}$  From an address delivered at the Lister Centenary Celebrations at Edinburgh on July 20

of abolishing the masses of dressings which were most in vogue in those days, and contented himself with applying a piece of dry lint over the line of incision and encouraging drying of the lymph and blood—that is to say, healing by scabbing. His example was followed by others, who tried to aid scabbing still further by blowing warm air over the wound at frequent intervals, or by the use of powders, dusting the line of incision with them.

About the same time Abernethy advocated with considerable success the use of valvular incisions in removing loose bodies from joints and in opening psoas abscesses

At the beginning of last century, subcutaneous surgery was introduced and Delpach elaborated it. Although its range of action was comparatively small, it still remains one of the important surgical methods of the day.

During last century a number of methods of treating wounds were introduced with a certain amount of improvement in results. Such methods were: open treatment, water dressing, immersion, water bath, irrigation, occlusion, etc. Just before Lister began his work, various substances, chiefly in solution, which belong to the class of antiseptics, eg. coal tar, carbolic acid, iodine, hypochlorites, perchloride of iron, etc., were being tried, especially in France. Of these, carbolic acid was lauded by Lemaire, but these antiseptics were only used in septic wounds, and Lemaire and others missed Lister's great generalisations which were the basis of his work

I may mention here Lister's 'slogans.'

1. Destroy the bacteria before they enter and establish themselves in the tissues.

2. Antiseptics are not used as applications to the tissues of the body laid open by the surgeon, but to the bacteria which are present everywhere, in the air and on the objects around.

3. Let as little as possible of the antiseptic enter the wound, but do not be unnecessarily afraid of it because, so long as the bacteria are kept out, any superficial damage done by the antiseptic will be rapidly repaired without any acute inflammation or suppuration.

4. The failure of the previous attempts with antiseptics was due to the fact that they were applied to wounds in which bacteria had already gained a footing and, as there is very little chance of eradicating the bacteria at that stage, irritating antiseptics like carbolic acid only make matters worse

One would have thought that these principles.

were clear and, when taken along with the published results, would have been very convincing. It always was a great puzzle to Lister's staff that surgeons did not rush to Lister's clinic to see his results and to learn his technique. True, there were always some foreigners, chiefly Germans and others of the Scandinavian races present in Edmburgh, but the number of British surgeons was very small indeed. Thus, when Lister migrated to London in 1877 (eleven years after his first publication), the number of London surgeons who were using his methods or were impressed by his teaching was extremely small and could probably be counted on the fingers of the hands.

It is not easy to account for this state of matters. Among other things it was very difficult to convince surgeons that tiny pieces of protoplasm about  $\frac{1}{20000}$  inch in diameter could be the cause of the septic diseases; the surgeons of that day were interested in keeping up their anatomy and in acquiring great rapidity in operating, and minute germs and processes of fermentation seemed very far removed from practical work; before Lister's time, carbolic acid and other chemicals had been applied to wounds without any benefit.

Lister's statement as to what he had achieved was so contrary to the experience of other surgeons that they felt that there must be a fallacy somewhere, and they were quite sure that the fault did not lie with them They noted that Lister was constantly changing his technique and dressings, and came to the conclusion that this was because his results were not good. They apparently did not listen to his statements, that he did so with the object of reducing or removing the irritation of the antiseptic and at the same time simplifying his technique They also pointed out that primary union of wounds was not a very uncommon occurrence before Lister's time, but they ignored his statement that it was the rule in his wards, they further pointed out the disagreeable effects of carbolic acid on the hands of the surgeon and its occasional poisonous effects

In spite, however, of these and other objections which need not be recalled, Lister went on with his work. When he retired there was little to find fault with as regards irritation of the wounds or skin by the antiseptics, and sepsis had become a matter of the rarest occurrence when his methods were adhered to rigidly.

### News and Views.

To the exhibition galleries of the British Museum (Natural History) have recently been added two exhibits of exceptional interest, both concerned with the elephant family but otherwise quite different. In the Palæontological Gallery has been erected the huge skeleton of the great fossil elephant which was brought to light by a party of Royal Engineers when digging practice trenches by the Medway opposite Chatham Dockyard about 1911. The importance of the bones that had been dug up was, however, not realised until 1913, when Mr. S. Turner sent some of the bones to the Natural History Museum for identification. Efforts were then made to secure the whole of the skeleton that remained, and Mr. L. E. Parsons, under the supervision of the late Dr. C. W. Andrews, spent several months at Upnor carefully excavating and packing the specimens for removal to the Museum. Further work was necessarily prevented by the War, and afterwards progress was gravely hindered by the death of Dr. Andrews. Fortunately, Mr. C. Forster Cooper, of Cambridge, a well-known authority on this group of fossils, lent his aid, and Dr. W. Rushton Parker generously defrayed the heavy cost of the ıronwork fitting. Finally, in spite of the difficult times, money was found for the base and the rail, and at last, after fourteen years, the public are enabled to see the remains of this huge creature, which stood over 12 feet high.

The other noteworthy new exhibit in the Natural History Museum is a habitat group of the South African elephant (*Elephas africanus capensis*), once widely distributed over South Africa but now nearly extinct. At the time of the destruction of the Addo Bush herd, the Union Government presented the Trustees with the skin and skull of an immature

female and of a young male from the Addo Bush, and of an immature male from Knysna Forest. These three specimens, which were mounted in the Rowland Ward studios, compose the group, and the scene has been laid in the Knysna Forest because of its greater picturesqueness. The Union Government enhanced the value of the gift by the addition of timber -yellowwood (Podocarpus elongata) and ironwood (Olea laurifolia)—and vegetation—tree-fern (Hemitelia capensis), fern (Aspidium capense), palm (Strelitzia augusta), and "Tangles" (Helichrysum)-all carefully collected and packed by the Forestry Department The Thesen and Union Castle Steamship Companies generously conveyed the material free of charge from Knysna Harbour to Cape Town and thence to London respectively. The exhibit has been designed and arranged by Capt. J. G. Dollman, and the lighting effects planned by Dr. G. F. Herbert Smith.

On Thursday of this week, July 28, Sir William Thiselton-Dyer reached the age of eighty-four years, and his many friends rejoice to offer affectionate tribute to one who has done so much to promote and extend the plant resources of the British Empire. Nearly two years ago (Sept 26, 1925) we published an appreciative article upon Sir William's work at the Royal Botanic Gardens, Kew, and its influence upon both pure and economic botany, and we are glad to know that its importance is widely recognised. He and Lady Thiselton-Dyer celebrated their golden wedding on June 23, and among the messages of congratulation were one from Mr. L. S. Amery, Secretary of State for the Colonies, and another from Prof. von Goebel, the doyen of German professors of botany. Mr. Amery referred appreciatively to Sir William's studies in the field of botanical enterprise,

British Williams

by which he has "rendered such valuable services in all corners of the Empire," and Prof von Goebel "It was you who first brought English and German botany into association which—serving as it does purely ideal aims-could not be destroyed by the War: and, further, we German botanists remember with gratitude the great services which you rendered with regard to Kew, with which in company with the two Hookers your name also will always be connected." It should be as encouraging to scientific workers generally as it is gratifying to Sir William Thiselton-Dyer to know that the seed of voluntary scientific service, such as was sown by him during many years, has borne rich fruits for the benefit of the human race, and that its value is understood in many lands

International relations in the chemical industries figured prominently in the report of the Council of the Association of British Chemical Manufacturers, adopted at its eleventh annual general meeting on The chairman, Mr C. A Hill, declared that undoubted advantages, from an international point of view, would accrue from the existence of a firm of the size and importance of Imperial Chemical Industries, Ltd: he referred also to the fact that the Association has joined the British National Committee of the International Chamber of Commerce, which has just held a conference in Stockholm, and to the conversations which have taken place between representatives of the Federation of British Industries and those of corresponding organisations in France, Germany, and Italy. These conferences, which are associated with the League of Nations Economic Conference at Geneva, afford an opportunity, which appears to have been effectively used, of securing to chemical industry in Great Britain a voice in the discussion of concrete matters of material concern, as well as of bringing it into closer touch with the trend of thought and outlook elsewhere. In speaking of domestic legislation, the chairman expressed relief that the proposed Factories (No. 2) Bill has been dropped; the much discussed 'petrol tax' which, however, is not proposed in the present budget, can scarcely exclude benzole, the taxation of which would have a disastrous effect on the dyestuffs section of chemical industry. References were also made to the effects of the Rating and Valuation Act 1925, the Merchandise Marks Act 1926, the Safeguarding of Industries Act, the Therapeutic Substances Act, and to Regulations concerning preservatives in food.

The production of a monograph on the chemical industry of the world from the British point of view within ten days of the appearance at Geneva of a corresponding German publication was described by the vice-president of the Association of British Chemical Manufacturers, Mr. Perry, as a brilliant piece of work. In the discussion which ensued, Mr T. Morson advocated the conferring of municipal franchise on corporations and companies, and spoke of the increasing cost of national social services, a subject which was further elaborated by the Right

Hon. J. W Wilson Sir John Brunner, who gave an account of his recent visit to Berlin, said that the main discussions converged on restrictions on imports and exports; on the whole, there is a tendency in Germany to ask that such restrictions should everywhere cease Tariffs were also examined from the point of view of classification and nomenclature; double taxation in Germany and England is another great hindrance to international trade Fairs and exhibitions, it is generally felt, are overdone, and the opinion has been expressed that they are largely becoming a question of blackmail among the traders of various countries. Mr. F. H Carr said that although the intention of the Therapeutic Substances Act is entirely benevolent, it may, if properly handled, do much to build up a branch of chemical industry which, whilst now in its infancy, has an immense future. Considerable satisfaction was expressed by Sir William Pearce in regard to the great improvement which has taken place in the position of the chemical industries since the end of the War.

THE University of Leyden has once more done honour to the Dutch physicians, biologists, and instrument-makers of the seventeenth and eighteenth centuries, by holding a special exhibition of their portraits and scientific instruments in the physical laboratory of the University on the occasion of the sixth Congress of the History of Medicine, held on July 18-23 in Leyden and Amsterdam Drs. C. A. Crommelin, W. P. Jorissen, C. J. Van der Klaauw, and W. H Van Seters have collaborated in producing a catalogue of the 139 objects exhibited in illustration of the work of 's Gravesande, the Munchenbroecks, Huygens, Leeuwenhoek, and Swammerdam. Two of the exhibits, two object glasses made by Constantijn Huygens, junior, and signed by him "C. Huygens, 10 May 1686, Ped. 122" and "C. Huygens, 19 Jun. 1686, Ped. 84," are of great interest, because they are accurately dated documents which, taken in conjunction with the three object glasses in the possession of the Royal Society of London, and dated June 4, June 26, and July 23, 1686, are evidence of the great industry and rapidity of working of the maker. We also note the reappearance of a quadrant made by J. M. Kleman for Boerhaave for use at his country house at Oud-Poelgeest. Although not stated in the catalogue, this quadrant, after being exhibited at Oxford in 1919, was given to the University of Leyden by the late Sir Wılliam Osler.

MM PIERRE and Gérard Deffontaines record in L'Anthropologie, t. 37, Nos. 1-2, the discovery of a Tardenoisian station at Cape Blanc-Nez, a little to the east of the road from Sangatte to Escalles. It is situated on a mound or small hill of tertiary sands overlying the chalk which in effect is a western terminal of the Flanders hills, and is sharply differentiated from the surrounding country by the distinctive character of its vegetation. It affords another example of the close association of the Tardenoisian microlithic culture with a sandy heath-like country. The authors suggest that while the microlithic industry

might be appropriate here to a mode of life which depended upon proximity to the sea, the association with sandy soil might be due to the facilities it afforded in a light soil for the beginnings of agriculture. This, while possible, would scarcely seem probable, and it is far more likely that both the association with this type of ground and the small implements of the industry are due to the character of a population which from necessity or choice had turned its hunting activities to small game as well as to fishing

It has been decided to erect a monument at Lyons to the late Count Hılaıre de Chardonnet, the 'Father' of the artificial silk industry Chardonnet was born at Besançon on May 1, 1839, and died at Rome on Mar. 12, 1924. Educated at Besançon, where he studied chemistry under Prof Loir, Pasteur's brotherin-law, he passed into the École Polytechnique at twenty years of age and afterwards devoted himself to scientific research. Many of his papers were read to the Paris Academy of Sciences His first patent in connexion with the production of artificial silk, taken out on May 12, 1884-"Sur une matière textile artificielle ressemblant à la soie "-was the result of his investigations between 1878 and 1884. 'Chardonnet' silk was exhibited at the Paris Exhibition in 1889, a factory was erected at Besançon soon after, and in 1891, 12 tons of the new material was produced. For 1926 the world's production of artificial silk was estimated at 120,000 tons.

THE central place in the proposed plan of a thorough survey of the natural resources of Armenia is given (as stated in the Information Bulletin of the Russian Academy of Sciences, No. 7-8, 1927) to the investigations in the basin of Lake Goktcha or Sevang. It is suggested that the waters of this enormous mountain lake might be utilised for irrigating vast tracts of lands which cannot at present be cultivated; but this is connected with the possible lowering of the level of the lake itself, and thorough hydrological studies of the lake will be undertaken with this view. It is taken into account also that the scheme may result in some changes in the climate of the surrounding country, so that thorough climatic studies will be also made. The soils and vegetation of the lands proposed for irrigation will be studied by several fieldparties in order to estimate definitely the agricultural value of the scheme. As the alteration in the regime of the lake cannot possibly be without its effects on its water fauna, a study of the latter, already in progress at the special hydrobiological station, will be continued on a larger scale and with the view of evolving a scientifically sound scheme of control of fisheries.

The paper on modern tramway equipment read by A. V. Mason to the recent congress at Bath of the Tramways and Light Railways Association is of interest as showing the difficulties in the way of tramway companies and how they propose to get over them. Owing to the speed of motor-cars it is considered that 25 miles per hour is a suitable normal speed for tramcars. A modern tramcar takes

150 yards from rest before its speed reaches this value, and then nearly another 150 yards to come to rest, if violent changes of speed are to be avoided. It takes from  $1\frac{1}{2}$  to 2 minutes to unload 90 passengers from a tramcar A motor omnibus is much more mobile. Everything to-day is being subordinated to speed. But speed needs power, and the starting current of modern tramcars is often more than 250 amperes, and this makes heavier supply mains necessary. On a day when skids are frequent the driver of a petrol vehicle goes slowly because he knows that the braking power is diminished. With a tramcar fitted with magnetic brakes, the driver runs at the same speed on all days as he knows by experience that the brake can always pull the car up quickly, and if the wheels skid they are released automatically. A recent improvement is to energise the magnetic brakes directly from the trolley wire. Unfortunately magnetic brakes tend to wear away the rails rapidly. When visiting Paris, Mr. Mason was impressed by the smooth running of the tramcars and the absence of all rattling noises. This is due to the brake being applied to a drum. In America the economic position is being straightened, wages have risen 120 per cent. on pre-War rates, and the fares have been increased 50 per cent. Successful experiments have been carried out on an all-aluminium car at Cleveland

Since the arrival in India of a farmer Vicerov the subject of animal husbandry has received a new stimulus, as is witnessed by the publication of a new periodical, The Journal of the Central Bureau for Animal Husbandry and Dairying in India, Part 1 of which has recently been issued. It opens with a foreword by Lord Irwin himself, breathing that active interest in livestock which his career in Great Britain leads us to expect "For the past two centuries," he says, "England's gentleman farmers have taken the lead in stock-breeding. . . . Let India's landed aristocracy follow their example"; and he rightly adds the reproof-"at present the tendency of the educated classes is to immerse themselves in politics or the law." The importance of the improvement of livestock in India cannot be exaggerated. A writer in the new journal estimates that the drain on the resources of the country caused by the enormous number of useless cattle maintained amounts to no less than 60 crores (upwards of 30 millions sterling annually). It is significant also to learn that although India is the country of the cow, the price of milk in Calcutta at the present time is 75 per cent. higher than the current retail price in London The improvement of the yielding capacity of the Indian cow is an obvious line of attack, and it is gratifying to learn that already considerable progress has been made in this direction. We wish this new venture the success which the importance of its subject fully deserves.

The most interesting of recent accessions to the Geological Department of the British Museum (Natural History) is a piece of rock from the immensely ancient Archæan rocks of Carelia, eastern Finland, presented

by the Director of the Finnish Geological Survey This rock displays a peculiar structure closely resembling some of the structures of approximately the same age in North America that have been described by the late C D Walcott as fossil Algæ. It has therefore been named Carelozoon jatulicum, and is by some experts regarded as evidence of life millions of years before the oldest known undoubted fossils. Among recent purchases are a few hundredweight of rough chunks of rock from Nevada; these are filled with ammonites of Middle Triassic age, as well as a few bones of an ichthyosaur. The specimens will be carefully extracted in the workshops of the department. Mr. F M Mackwood has presented to the Department of Entomology of the Museum sixty boxes of butterflies and moths, collected by himself ın Ceylon Included in the thirteen boxes of butterflies is a number of rarities, while the forty-seven boxes of moths form a welcome addition to the extensive collections of Ceylon moths already preserved in the Museum.

Among the objects figured in the recent Records of Additions to the Hull Museum, is an example of a bronze palstave. This form of bronze age axe, in which the cutting edge is at right angles to the septum between the flanges for hafting, as was noted by Sir John Evans, is of particular rarity in England. The Hull Museum specimen was recently found at Messingham in Lincolnshire. It is  $4\frac{1}{2}$  inches long, the cutting edge is slightly more than  $1\frac{1}{2}$  inches in length, and the implement weighs 5 oz. Unlike the two figured by Sir John Evans, which were fairly straight in the shaft, it has a well-shaped semi-lunar cutting edge resembling an Irish example also figured by Sir John Evans.

A COMMITTEE representative of agricultural interests in the northern counties of Great Britain, and under the chairmanship of the Duke of Northumberland, has issued an appeal for a fund for a memorial to the late Prof. Douglas A. Gilchrist, who died on April 4 shortly after his retirement from the chair of agriculture at Armstrong College, Newcastle-on-Tyne. The memorial will probably consist of a scholarship at Armstrong College for post-graduate students in agricultural science, or, should the fund be insufficient, for the award of a prize or prizes to agricultural students. Contributions may be sent to the honorary secretary, Mr. C. Williams, The Moothall, Newcastle-upon-Tyne.

APPLICATIONS are being invited by the Institution of Civil Engineers until Sept. 16 for the Yarrow and William Lindley scholarships. Applicants for the Yarrow scholarships must be British subjects who are not more than twenty-three years of age and who, desiring to become engineers, lack sufficient means to enable them to pursue their practical training or their scientific education. The scholarships are ordinarily of values from £50-£100 per annum for one, two, or three years. Applicants for the William Lindley scholarships must not be more than twenty-three years of age, and must be children of corporate members of the Institution

whose means are madequate to defray all the expenses incidental to an engineering training. The fund provides for (a) a major scholarship of £80 per annum for engineering study at the University of Cambridge, tenable for three years, and (b) a scholarship of £40 per annum for scientific education or practical training in engineering.

THE Library of the Chemical Society will be closed for stocktaking from Monday, Aug 1, until Saturday. Aug 13 inclusive, and will close each evening at 5 o'clock on Aug. 15—Sept. 10.

By arrangement with the London County Council, the Imperial Institute cimema will be open from 2 40 PM. to 5 30 P.M. on Sundays for the free display of films relating to the life and industries of the Dominions, India, the Colonies and Protectorates. The cinema is open free on week-days from 10.30 A.M. to 12.30 P.M. and from 2.30 P.M. to 4.30 P.M.

Mr. J. C. RICHARDSON, 74 Storemont Road, London, S W.11, writes to say that quicklime which has been soaked in petroleum, in contact with a little water evolves so much heat that the oil is readily ignited. This effect was probably used in the ancient incendiary mixtures, since the "Liber ignium" (twelfth century MS) describes the effect noticed by Mr. Richardson (R. calcem vivam . . . cum oleo . . aqua aspersa accendetur).

THE Astronomer Royal has arranged for the supply of enlarged photographic prints of the fine picture of solar prominences and inner corona secured at Giggleswick during the total eclipse of the sun on July 29. The moon's disc on the picture is  $7\frac{1}{2}$  inches in diameter, and the structure of the prominences and corona is remarkably fine and clear on the piint. Copies may be obtained, at the price of 2s. 6d. each. upon application to Mr F Jeffries, Royal Observatory. Greenwich, London, S.E 10.

ANOTHER of the important catalogues of second-hand science books (No. 409) of Messrs. Bernard Quartch, Ltd., 11 Grafton Street, W.1, has just been circulated. As usual it gives particulars of many choice and rare volumes. The contents are arranged under the sections of botany, agriculture, early medicine and surgery, forestry, fruit-culture, gardens and gardening, herbals, modern medicine, and tobacco.

Messrs Dulau and Co , Ltd., 32 Old Bond Street, W.1, have just issued a very interesting and important catalogue (No. 150) of works on science published prior to 1800. It gives particulars of upwards of 400 volumes dealing with botany, horticulture, agriculture and herbals, general natural history, medicine, astronomy, mathematics, sundials, etc. Many of the works listed are extremely rare. The catalogue, which can be had upon application, is worthy of perusal.

On every hand the development of scientific control brings in its train new methods of analysis and testing, and eventually convention crystallises into standardisation. Instrument makers must exert themselves to keep pace with the supply of the necessary equipment, and what this involves may be seen from the catalogue dealing with the "Analysis of Coal and its By-Products," just issued by Baird and Tatlock (London), Ltd. It has 136 quarto pages, is illustrated, and seems to include more than most of those interested in fuel analysis are likely to require. Thoughtfully, the proposed standardised methods of coal analysis are included in summarised form, and also a variety of useful information, presumably to encourage us to look inside as often as possible. A catalogue of "Apparatus for Testing Petroleum Products" stocked by the same firm occupies 44 pages and covers the requirements of the tests of the Institution of Petroleum Technologists.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned .- A temporary lecturer in agriculture under the Wilts County Council Agricultural Committee—The Organiser of Agricultural Education, Polebarn House, Trowbridge (Aug. 6). A junior assistant in the department of civil engineering of the Queen's University of Belfast-Prof. Hummel, The Queen's University, Belfast (Aug. 13). A director of the School of Egyptian Arts and Crafts, Cairo—The Under-Secretary of State, Ministry of Education, Cairo, Egypt (Aug. 15). An assistant lecturer in mathematics in the Bradford Technical College—The Principal, Bradford Technical College, Bradford (Aug. 23). An assistant woman lecturer and demonstrator in botany and an assistant woman demonstrator in physics at the Royal Holloway

College—The Principal, Royal Holloway College, Three posts at Englefield Green, Surrey (Aug 25) the Royal Veterinary College, namely, a principal, a director of the Research Institute in Animal Pathology, and a professor of pathology—The Secretary, Royal Vetermary College, Camden Town, S W.1 (Aug. 31). A professor of English language and literature in the University of Melbourne—The Agent-General for Victoria, Victoria House, Melbourne Place, W.C.2 (Oct. 1). Two research scholars at the John Innes Horticultural Institution—one, a botanist, to work at genetic and cytological problems, and one, a chemist. to work at problems of migration and storage with the plant—The Director, John Innes Horticultural Institution, Merton, S W.19. An assistant lecturer in physics in the University College of the South-West of England —The Registrar, University College of the South-West ot England, Exeter. Evening lecturers at the Croydon Polytechnic for electrical generation and transmission, advanced building construction and quantity surveying—The Principal, Croydon Polytechnic, Scarbrook-Road, Croydon. A science master at the Leods Grammar School - The Headmaster's Secretary, Grammar School, Leeds. A chief lecturer to take charge of the chemical department of the Woolwich Polytechnic-The Principal, Woolwich Polytechnic, S.E.18. A junior assistant under the directorate of Metallurgical Research, Research Department, Woolwich-The Chief Superintendent, Research Department, Woolwich, S.E.18.

### Our Astronomical Column.

RECENT MAGNETIC DISTURBANCE.—A considerable magnetic disturbance, lasting about 9 hours, was registered between July 21 and 22 at Greenwich and at Abinger, Surrey. The disturbance, which commenced suddenly at 21<sup>h</sup> on July 21, reached its greatest intensity between 2<sup>h</sup> and 5<sup>h</sup> on the following morning and died away rapidly soon after 6<sup>h</sup>. The excursion shown by the declination magnet amounted to fully one degree. The disturbance was also well shown by the vertical force magnetometer.

A superficial examination of the sun's disc showed no spots likely to be connected with this disturbance At 21h on July 21, there were three unimportant groups of spots at distances of 38° west, 7° east, and 48° east of the sun's central meridian. A large regular spot was a little way on the disc at a distance of 78° east of the central meridian. It is possible, however, that spectroscopic observations may come to hand as an indication of an usually active region on the sun not represented by a sunspot, and at the time placed somewhere in line with the earth.

The Planet Jupiter.—Mr. W. F. Denning writes: "This planet may now be well observed, as it rises at the end of July at 9h 37m p.m. G.M.T., and will shortly be in view throughout the night as it comes above the horizon four minutes earlier daily, and arrives at opposition on Sept. 22. Mr. F. Sargent, of the University of Durham Observatory, states, in a letter to me, that he obtained a good observation of the planet's markings on the night of July 18 with a 10½-inch reflecting telescope. He says the Red Spot is really true to its name in colour, for it is a bright, brick red. It is quite an obvious, easy feature. By comparison with an observation by the Rev. T. E. R. Phillips on July 21, 1926, he found that the rotation period, during the past 12 months, was 9h 55m 37s, whereas the previous 12 months gave

9h 55m 33s, or 4 seconds less. The direct inference is that the motion of the object has recently undergone a considerable slackening in its rate of motion. Following the Red Spot there is a distinct prolongation of the south-temperate belt which bends northwards towards the south margin of the south equatorial belt. Mr. Sargent observed several dark and white spots on the margin of the north equatorial belt and states that according to his estimates the length of the Red Spot is now only 20°, but one boundary of the marking appears to be indefinite. Forty or fifty years ago the length of the spot was about 32°."

A DISCUSSION OF STELLAR VARIABILITY.—Prof. C. D. Perrine contributes a discussion on this subject to Astr. Nach. No. 5505 His argument is that all types of stellar variation are due to a common cause which he takes to be pulsation of the type now generally assumed to explain Cepheid variables. It is rather curious that Prof Perrine for a long time upheld the binary character of the Cepheids; in abandoning this explanation for these variables, he also abandons it for stars where it seems to be well established. For example, the duplicity of Capella was confirmed by the interferometer, and the eclipse explanation of Algol's light changes was confirmed by the fact that the rotation of the principal star could be measured by the Doppler effect (the two limbs being successively under observation) The results fitted in harmoniously with the binary hypothesis.

Prof. Perrine reaches his conclusion by grouping all the known variables by period and light-range and showing that they lie along continuous curves, each type filling up gaps left by the others. Probably few will adopt his new conclusions in their entirety, but statistical discussions of this kind are always of value,

and afford material for further study.

### Research Items.

SKELETAL RECORDS OF MORTALITY.—An investigation in which the method is at least as interesting as the results, is recorded by Prof. T. Wingate Todd in the Scientific Monthly for June. Since 1912 the anatomical laboratory of Western Reserve University has preserved the skeletons of all subjects, of both white and negro stock, delivered to the medical school, together with a record of the age of each individual An intensive study of this material, now 1400 specimens, with the view of determining appearances related to age, has made it possible to fix more accurately than hitherto the age at which death took place in any individual case, by an examination of the skeleton It thus becomes possible, by applying this method to the study of skeletal remains for which a record of the age of death is not available, to determine with approximate accuracy the incidence of mortality. For the present investigation an examination has been made of the material already mentioned in the Medical School, West African skulls in the Royal College of Surgeons, the Tasmanian skulls in the same collection, bronze age skeletons from Furness, medieval remains from Scarborough, and skeletal material ranging in date from A.D. 800 to A.D. 1000 from Pecos in New Mexico. Data for Rome and the Roman colonies in Africa and Spain for comparative purposes are taken from Macdonell's study of expectation of life in Rome, which was based upon the epitaphs of the "Corpus Inscriptionum Latinarum" of the Berlin Academy. In each case interesting results emerge, but the general conclusion is perhaps most significant. The data relating to primitive and early races alike fail to show the peak of death in senility which Pearson found in the mortality curve for England. The peak of mortality occurs at a moderately early age. The peak of old-age death is therefore a comparatively modern achievement resulting from greater safety and improved conditions of living. It differs from the peak of mortality in early and primitive peoples by roughly thirty years.

ANTHROPOMETRY OF NORTH AMERICAN INDIANS.-A continuation of Dr. Aleš Hrdlička's catalogue of human crania in the United States National Museum has been published as vol. 69, art. 5 of the Proceedings of the Museum. This part is the second to be issued, the first having appeared in 1924 as art. 12 of vol. 63. It covers: Algonkin and related Iroquois (563 crania), Siouan (285 crania), the Caddoes (15 crania), the Salish and Sahaptin (15 crania), the Shoshonean (69 crama), and the Californians (403 crama). In addition the author's records of crama in other institutions have been added. Of the different strains, the Algonkin shows almost throughout a distinct physical character, coinciding almost exactly with the linguistic family; while the Iroquois, though of different linguistic stock, and including some heterogeneous elements, are radically of the same physical type—dolichocephalic to mesocephalic, with high vault, medium to large face, medium to low orbits, and medium to relatively narrow nose. Sioux type, one of the best differentiated on the continent, has a mesocephalic skull of moderate to good size, a remarkably low vault-met with only in Athapascans and north-west coast tribes, and distantly among the Mongols—large face and jaws, medium to high orbits, and is mesorhine. The Californian tribes show considerable uniformity, are practically identical with the Shoshonean, and exhibit no traces of extraneous (non-Indian) influence.

THE THAMES AND THE RHINE.—The belief that the Thames and other English rivers were once tributaries

of the Rhine and that the combined rivers flowed northward to the Arctic Ocean over a plain now occupied by the North Sea, has long been accepted. Jukes Browne put the Arctic outlet north of the Shetlands; Clement Reid put it nearer the Humber; and there have been other modifications in detail. Prof. J. W. Gregory re-examines the problem in an article in the Geographical Journal for July, bringing new evidence from the fauna of the rivers and the hydrography of the North Sea. His paper is full of detail and can only be followed with the help of its maps, but the conclusion at which Prof. Gregory arrives is that the Thames did not join the Rhine but turned south through the Dover gate and west along the course of the present English channel, joined by the Hampshire rivers and the Seine. The Rhine flowed through the Zuyder Zee and was separated from the Thames by a land barrier in the North Sea plain now recognisable as a rise on the sea floor, which Prof. Gregory terms the Haisboro-Terschelling The rivers of the Wash and Humber probably joined the Rhine, which flowed westward of the Dogger Bank into the sea and possibly continued to the Norwegian trench. In either case, it would not have been connected with the rivers of Scotland. It is suggested that the land extended northwards only to the 40-fathom and not the 100-fathom line

AUSTRALIAN AGRICULTURAL RESEARCH.—F McDougall and A. S. Fitzpatrick, in Vol. 10, No. 2, of the Scottish Journal of Agriculture, give an account of agricultural research in Australia. The problems of the country are extremely diverse on account of the wide range in the climatic conditions and the variety of industries which are therefore possible. Both agricultural and pastoral industries have increased enormously in the last few years, but as hitherto farming has been on an extensive rather than intensive scale, and as only a small proportion of workable land is actually under cultivation, the scope for future development is large. The chief industry is wool production, and attention to sheep breeding on scientific lines has resulted in a striking increase in the yield of wool; for example, the average weight of fleece per sheep in 1850 was less than 4 lb., whereas m 1925 it averaged 7 69 lb. Wheat growing is the second important industry. Improvements in plant breeding and better methods of dry farming have considerably extended the wheat belt, and the possible wheat-growing area is now estimated at double that at present bearing that crop. Fruit affords many specialised problems. Besides investigations on diseases and insect pests, the suitability of various soils for irrigation and the study of the effect of green manuring on soil fertility are two of the more important lines of work. The biological control of serious weeds, such as the prickly pear, by means of the introduction of certain insects, seems to be proving entirely successful. Dairying, another important industry, can be carried on throughout almost the entire country; similar problems can, therefore, be studied under widely varying climatic conditions. Deficiency in the mineral content of pastures is thought to have a possible correlation with a number of animal diseases, and owing to the importance of the meat export trade the question is being thoroughly investigated. Research is being conducted under two organisations working in close collaboration, namely, the Commonwealth Council for Scientific and Industrial Research, which deals with the scientific aspects of the industries, and the Development and Migration Commission, which is concerned with the economic conditions of the country.

THE LIMBS OF CRUSTACEA AND TRILOBITES.—In their recent paper on the feeding mechanism of a mysid (Trans. R Soc. Edin vol. 55, 1927) Prof H G Cannon and Miss S M Manton criticise Storch's views on the evolution of the feeding limbs of the Crustacea and Trilobites While Storch considers the primitive crustacean feeding limb to have been a phyllopodium similar to that of the Anostraca, and to have functioned essentially as a filtering mechanism, they suggest that the primitive limb was a biramous paddle such as occurs in the posterior trunk segments of Lepidocaris. From primitive articulates possessing biramous limbs the authors consider that the Branchiopoda and other Crustacea evolved from forms in which the limbs projected ventrally from the body in two parallel series, while Marella and the Trilobites arose from forms in which the limbs projected laterally. Among the Crustacea the endopodite became a foliaceous swimming organ in the Branchiopoda, while in the Malacostraca the exopodite developed as the swimming part of the limb, but it became whiplike. In Marella and the Trilobites the exopodite became the swimming branch of the limb. The authors agree with the usually accepted homologies of the two branches of the limbs of Trilobites, they do not accept the suggestion of Storch for the 'reversal' of the endopodite and exopodite

A Burrowing Cirripede.—Major R B. Seymour Sewell (*Records Indian Mus.*, **28**, pp. 269-330, 1926) has made a detailed study of *Lithotrya nicobarica*, a cirripede which burrows in coral or coral conglomerate usually in such a position that the head, or capitellum, hangs vertically downwards. The author obtained in the Nicobar Islands 65 examples of this species the largest series hitherto obtained, and was therefore able to study the range of variation. The specimens were found to fall into four groups, which he believes to represent age-groups each corresponding to a year's growth. It would appear that the average length of life of the members of this species is about three years, but that a certain number of individuals may survive for a fourth year. Major Sewell gives a detailed description of the external characters, including the appendages, and of the alimentary tract, the nervous system, and the reproductive apparatus. All the species of Lithotrya appear to be hermaphrodite and are probably protandrous; no complemental or parasitic males have been observed in this A consideration of the changes that occur in individuals of L. nicobarica as age and size increase suggests that several so-called species, which have hitherto been regarded as distinct, are merely different varieties or life-phases of a single widely distributed The author records a distinct tendency towards 'right-handedness' in the capitellum indicated by the fact that the scales or laminæ of both scutum and tergum are rubbed off to a greater degree on the right side than on the left. The greater development of the longitudinal peduncular muscles on the right side would seem to be associated with the 'right-handedness' since the more violent movement of this side of the body would cause a more rapid removal of the older laminæ.

Marine Shells from the South-east Coast of the United States.—In 1885 and 1886 the U.S. Fisheries Steamer Albatross made a series of dredgings off the south-east coast of the United States. The larger specimens of mollusca have been already dealt with, but the examples from the fine siftings were reserved and worked at from time to time, as opportunity served, by the late Dr. W. H. Dall, the Pyramidellidæ being determined by Dr. P. Bartsch. The descriptions of these are now published (Proc.

U.S. Nat. Mus., vol. 70, art. 18) and account for 337 species, of which 204 are apparently new. Unfortunately, none of these new forms is at present figured.

HEREDITARY OBESITY IN MICE —It is well known that in mice, yellow is epistatic to other coat colours and that homozygous yellow mice do not occur owing to the lethal effect of the yellow gene in the homozygous condition. Dr Danforth has recently shown (Jour of Heredity, vol 18, No. 4) that healthy yellow mice always become abnormally fat on an ordinary diet, this tendency being even more marked in the females than in the males. Thus yellow females are often twice, and sometimes thrice, as heavy as others. The fat is partly subcutaneous and partly attached to the viscera. The evidence indicates that the obesity is produced by the same gene which produces the yellow coat pigmentation and not by a separate factor, since no cross-overs appear On a restricted diet the yellow mice can gradually use up their store of fat, and it is suggested that the condition is similar to that in hibernating animals which store up fat in their tissues to be used later when no food is The condition is also compared with that in certain human families with a pronounced hereditary tendency to adiposity.

The Armenian Earthquake of Oct 22, 1926.—This destructive earthquake is described in a brief report by Prof S. Abdalian of the University of Erivan (La Nature, July 1). The epicentre was near Panyantour in the recently depressed valley of the Chirak. Several important faults traverse this valley, one of them running close to the volcano Alaghoz (about 15,000 feet in height). In the epicentral district the ground was much fissured, and in one fissure, passing through the village of Alexandrooka, a change of level of 15 mm. has occurred, the side next the valley being depressed with reference to the side of Alaghoz. At Dharh and Kazarabad, monuments in the cemeteries were rotated on their pedestals through an angle of 43°.

ICE ON THE COAST OF FINLAND.—The distribution of ice on the Finnish coast of the Gulf of Bothma, the Gulf of Finland, and Lake Ladoga, year by year, is recorded in a series of papers published by the Havsforskningsinstitutet of Helsingfors, entitled Oversikt av Isaona. They cover the winters 1914–15, 1915–16, 1917–18, 1919–1920, 1924–25. Reports for the other years have already been published. In a series of maps the nature and distribution of the ice is shown during the winter months. Freezing generally begins in November, and the ice has its widest extent in March, in April conditions improve, but the break up and disappearance of the ice is slow. Some of it may be present so late as June, but as a rule it has gone before the end of May. In some years January and February are little better than March. The data on which the distribution charts are based are collected by some seventy stations along the coast and in the Aland Islands. The reports also give the air and water temperature for representative stations during the winter months.

Hydrography of the Labrador Banks—The report for 1926 of the International Ice Observation and Ice Patrol in the North Atlantic (United States Coast Guard Bulletin, No. 15) gives an account of some oceanographical researches in addition to the itineraries of the patrol vessels and location of the icebergs. The observations for 1926 corroborate earlier ones to the effect that the density of water on the Grand Bank is usually higher along the zone of contact between

the Labrador Current and the Culf Stream than on either side of the Gulf Stream. But this high density does not exactly coincide with the abrupt transition from low to high temperature, but hes as a rule 25 miles to 35 miles inshore of it. Since the density wall unquestionably marks the easterly and the westerly sets of the Currents, it follows that the drop in temperature of the surface water does not mark the change in direction of the current. Another section gives a summary of neeberg records off Newfoundland between 1880 and 1926, with particular reference to the past twenty-six years, the records of which are plotted on a chart. It is shown that there are no ice-free months on the steamer tracks via Cape Race and only four on the tracks between the United States and Europe.

Molecular Spectra.—The band spectra of the vapours of sulphur, selenium, and tellurium, which were the subject of a recent paper by Prof. McLennan in the Philosophical Magazine, have been examined in more detail by B. Rosen in Berlin (Zeitschrift für Physik, 43, p 69) The resonance series and the fluorescence and absorption spectra are similar to those found in iodine by Prof. R. W. Wood, and are likewise ascribed to a simple diatomic molecule. Addition of inert gases to tellurium does not, however, increase the number of lines obtained in resonance, as it does with iodine, but merely reduces the intensity of those already present. The analysis of these spectra gives considerable information about the forces between the two nuclei and the heat of dissociation into atoms, as well as the conditions under which Stokes's rule, that the excited light is of greater wave-length than the incident light, breaks down

THE LIGHT FROM POSITIVE RAYS -Prof. W. Wien has recently succeeded in photographing the first five members of the fundamental Lyman series of hydrogen in the ultra-violet light from positive rays which had passed through a perforated cathode (Annalen der Physik, vol. 83, p. 1). His usual technique had to be considerably modified, the pencil of positive rays being shot excentrically into the barrel of a vacuum spectrograph, where its image was thrown directly by the grating on to a Schumann plate. The calibration of the plate for quantitative measurements of intensity was effected by intercepting part of the positive rays, and measuring the current carried by the remainder to a small metal disc, the corresponding spectra being examined afterwards by ordinary photometric methods. Prof. Wien's photographs show very clearly the decrease in the luminosity of the beam as it passes away from the cathode.  $H_a$  and  $H_b$  have the same decay constant, and the failure of the classical theory of radiation from accelerated electrons is again demonstrated by the incorrect relation which it predicts between the damping factors in this case, and in the allied Balmer series The grating used by Prof. Wien was ruled at the National Physical Laboratory, Teddington, on a blank supplied by Messrs. Adam Hilger.

Properties of Metals at High Temperatures.—Part of a research carried out at the National Physical Laboratory by Messrs. Tapsell and Clenshaw on this subject is published in a pamphlet issued by H M. Stationery Office, price 1s. 9d. Three metals are discussed: Armo iron and two steels with 0·17 and 0·24 per cent carbon respectively. All the more important mechanical properties have been measured up to about 600° or 700° C. Although there is no fundamentally new result, the values which have been determined for the creep and fatigue strengths at

these temperatures will be examined with care by those engineers to whom the strength of steel at high temperatures is becoming of minediate importance. So far as the limiting creep strength is concerned there is a progressive fall as the temperature is raised, for the mild steels from about 35 tons per sq. m. at 250° C to 5 tons at 500° C. The fatigue strength falls slightly as the temperature rises above the normal to a minimum at 150° C., from  $\pm 13$  to  $\pm 12$  tons per sq. m., then rises rapidly to  $\pm 17$  5 tons per sq. in. at about 450° C., and afterwards falls off to  $\pm 7$  tons per sq. m. at 600° C., the highest temperature used. There are many useful tables of test data and curves and a continuation of the work will be looked forward to with keen interest.

METALLURGICAL MICROSCOPES.—The latest edition of the catalogue of microscopes and accessories for metallurgical work issued by Messrs W. Watson and Sons, Ltd, contains in addition to the already wellknown forms of stands manufactured by them a new model "Service" microscope with one or two novel features. Most noteworthy of these is the stage. which may be swung out so that the stand may be used to examine large metallurgical samples too heavy to be placed on the stage For ordinary works' use this model would appear to be eminently suitable. A form of microscope designed in conjunction with Messis. Vickers, Ltd., for industrial use is illustrated and should appeal to those carrying out routine work of a high order. A projection cabinet designed by Mr. E A Atkins for demonstration and similar purposes is shown, and, where foremen and others are given some idea of microstructures, this would seem to be a piece of apparatus admirably suited to its purpose.

THE THOMAS GAS METER.—This meter, made by the Cambridge Instrument Co, Ltd., and designed primarily for the accurate measurement of industrial or towns' gas, in terms of standard cubic feet of moist gas measured at standard temperature (60° F) and standard pressure (30 inches of mercury) utilises the fact that the specific heat per unit volume of such gases is practically constant throughout the variations of pressure, temperature, density, and composition which occur in gas practice. The stream of gas flowing past an electric heater inserted in the gas main is heated exactly through 2° F., the difference of temperature being determined by two platinum thermometers inserted one on either side of the heater and forming two arms of a Wheatstone bridge. Under these conditions the energy input to the heater, measured on a wattmeter, is an accurate measure of the rate of flow of gas in the main. In order to maintain the bridge in balance with the two thermometers differing by 2° F., a third compensating thermometer, having a resistance equal to the difference of the first two, is inserted in the appropriate arm of the bridge. This temperature - difference thermometer also corrects automatically for variations of the water vapour content of the gas. Throughout, with varying flow, the bridge is maintained balanced and the energy input necessary to maintain the  $2^{\circ}$  F. difference of temperature varied automatically and recorded by an integrating wattmeter. If the gas flow ceases the meter is automatically put out of action. The meter is made in two standard formsthe return flow type, in which the meter is jacketted by the gas; and the vertical type, in which the meter is jacketted by a dead space containing gas. There are fourteen standard sizes, having maximum capacities ranging from 25,000 cubic feet per hour upwards. About 300 meters of this type are in use in various parts of the world.

## The Constitution and Synthesis of Thyroxine.

ABOUT a year ago we reserved to the work of Harington on the isolation of the active principle of the thyroid gland and the constitution and synthesis of its first degradation product, desiodo-thyroxine (NATURE, July 10, 1926, vol. 118, p. 65) A recent paper by Harington and Barger now completes this important piece of work by proving the constitution of thyroxine itself and describing a method for its synthesis (C. R. Harington and O. Barger, Biochem. Journ., 1927, vol. 21, p. 169). The formula for the compound, as suggested by the previous work and proved in the present research, shows that it is a tetra-iodo derivative of the p-hydroxyphenyl ether of tyrosine:

$$HO \left\langle \begin{array}{c} I \\ \\ I \end{array} \right\rangle O \left\langle \begin{array}{c} I \\ \\ I \end{array} \right\rangle CH_2 \cdot CH(NH_2) \cdot COOH.$$

Previous work had proved the constitution of desiodothyroxin and its synthesis had been accomplished: the problem remaining was the position of the four rodine atoms in the molecule and their insertion by synthesis. Three considerations made it appear probable that the rodine atoms occupied the positions given in the above formula: first, on fusing thyroxine with potash at a high temperature in the absence of oxygen, products were obtained exhibiting pyrogallol reactions, suggesting the presence of 3:4:5 trihydroxy benzene derivatives; secondly, nitrous acid and ammonia gave a colour reaction characteristic of benzene derivatives containing two iodine atoms in the ortho position to a hydroxyl or amino group; thirdly, on general grounds it appears probable that thyroxine is synthesised in Nature from tyrosine, through the coupling of two molecules of 3:5 duodotyrosine with the loss of one side-chain

Direct iodination of desiodothyroxine resulted in the uptake of two iodine atoms only, so that the introduction of the other two had to be effected before the phenylether synthesis was carried out. Several attempts were made to effect the synthesis, from compounds containing two iodine atoms or other easily replaceable groups in the required positions, of the body  $\mathrm{CH_3O.C_6H_2I_2.O.C_6H_2I_2.COOH}$  obtained by the methylation and subsequent oxidation of thyroxine, but without success.

Finally, however, a method was worked out, and the synthetic formation of this methylated oxidation product of thyroxine definitely proved the constitution of the latter. Quinol monomethyl ether was condensed with 3:4:5 triiodonitrobenzene, to give 3:5 diiodo - 4 - (4' methoxyphenoxy) nitrobenzene:

CH<sub>3</sub>O . C<sub>6</sub>H<sub>4</sub> . O . C<sub>8</sub>H<sub>2</sub>I<sub>2</sub> . NO<sub>2</sub> (the NO<sub>2</sub> group having a powerful mobilising effect on the halogen atom in the para position) This compound was then reduced to the anilme and the latter converted, by Sandmeyer's reaction, into the mirrle. The nitrile, boiled with hydriodic and acetic acids underwent simultaneous demethylation and hydrolysis, yielding the compound: HO . C<sub>6</sub>H<sub>4</sub> . O . C<sub>6</sub>H<sub>2</sub>I<sub>2</sub> . COOH; on addition of iodine in potassium iodide to a solution of the acid in concentrated ammonia, iodine was rapidly taken up, the uptake ceasing abruptly at two molecules. On methylation an acid, identical in every respect with that obtained by the methylation and oxidation of thyroxine, was produced. These experiments thus settled the orientation of the iodine atoms in thyroxine, since the last two, introduced in alkaline solution, must have entered the ortho positions to the free phenolic group

For the actual synthesis of thyroxine the starting-point was 3:5 diodo-4-(4' methoxyphenoxy) benzaldehyde; but it could not be condensed directly with a-aminopropionic acid, since the necessary reduction would displace the iodine atoms. Some success was attained by condensing it with hydantoin, but far better results were seen when hippuric acid was used. The resulting compound

$$\mathrm{CH_3O}$$
 .  $\mathrm{C_6H_4}$  .  $\mathrm{O}$  .  $\mathrm{C_6H_2I_2}$  .  $\mathrm{CH}$  :  $(\mathrm{C_3O_2N})$  .  $\mathrm{C_6II_5}$ 

was then converted into the  $\alpha$ -benzoylammo emmanic ester:

$$\mathrm{CH_{3}O} \cdot \mathrm{C}_{6}\mathrm{H}_{4} \cdot \mathrm{O} \cdot \mathrm{C}_{6}\mathrm{H}_{2}\mathrm{I}_{2} \cdot \mathrm{CH} : \mathrm{C(NH\cdot CO\cdot C}_{6}\mathrm{H}_{5}) \cup \mathrm{COCEt},$$

which, on boiling with hydriodic acid and red phosphorus, underwent demethylation and conversion of the side-chain into α-aminopropionic acid. The final stage of iodination in animonacal solution led to the uptake of two iodine atoms and the production of a compound identical in its chemical and physiological properties with natural thyroxine.

These two syntheses, then, establish finally the constitution of thyroxme. That the synthetic product has the same physiological properties as that isolated from the thyroid gland is shown in an appendix by D. M. Lyon: the basal metabolic rate of two cases of myxeedena was raised from about -40 per cent. to normal in the course of a week by three or four intravenous injections of 4-5 mgm. of the synthetic product on alternate days. These effects are quantitatively similar to those reported for natural thyroxine.

There can be no doubt, then, as to the identity of the artificial and natural thyroxines, and we can congratulate the authors on bringing their research to a successful conclusion.

### The Cockle Industry in Great Britain.

OUR knowledge of the edible shellfish of British coasts has been extended by Mr. F. S Wright in his "Report on the Cockle Beds and the Cockle Industry of England and Wales" (Fishery Investigations, Series 2, Vol. 9, No. 5, 1926. London: H.M. Stationery Office. 3s. net). Not only are his own investigations on the habits, bionomics, and growth of cockles of great value, but he has also done a great service by bringing together a mass of information on the subject which has hitherto been very scattered.

The economic value of the cockle is considerable, and its potential value even greater. Under the best conditions, when living in wet stable sand, cockles occur in vast numbers in comparatively small areas. Mr. Wright estimated that in one bed in the Llan-

rhidian Sands in South Wales, having an area of some 320 acres, there were present about four hundred and sixty-two million cockles of all sizes, the average number in each square metre being 357. A very interesting point brought out in the paper is that in some localities there are definite beds of young cockles which contain a dense population. As the cockles grow, many are forced to the surface, and those are then distributed over the general surface of the beds by the action of waves and currents. Though the enemies of the cockle include starfish, boring gastropods, gulls, and certain fish, the greatest danger to the beds comes from frost, storms, and currents, which may destroy great numbers of cockles in the winter months. The cockle gatherers themselves do

great damage with their rakes, and by leaving the young cockles which are too small for the market at the mercy of currents instead of scattering them over the beds where they can re-establish themselves By so doing they endanger their own livelihood as well as contravene the by-laws which regulate the cockle fisheries.

The chief centres of the cockle fishery in England and Wales are the Wash, the Thames Estuary, Carmarthen Bay, and Morecambe Bay. The cockles are gathered by raking, scraping, and digging, and are usually boiled, and the soft parts separated from the shells by sieving, before they are sent away to the market. The shells have a certain value, for they are often ground up to serve as grit for poultry.

Although it has not the high carbohydrate content of the native oyster, the food value of the cockle is considerable, and, in common with similar shellfish, it provides a valuable source of food the use of which might with great profit to the community be greatly extended. It is encouraging in this connexion to note that the annual quantity of cockles landed in Great Britain increased from 167,089 cwt. in 1923 to 300,721 cwt. m 1925, while probably many more were collected by casual gatherers. It is disconcerting, however, to learn that owing to the fact that English gatherers often refuse to take the trouble to pick out the larger cockles, which naturally command the best market, considerable quantities of cockles have been imported from Holland, where, apparently, the shellfish merchants pay more attention to the market C. M. Y.

# River Pollution and Fisheries.

DR. H. C. REDEKE has written a useful summary of the results of recent investigations upon the subject of river pollution for the International Council for the Exploration of the Sea (Rapports et Procès-Verbaux des Réunions, vol. 43, May. Copenhagen · Andr. Fred. Host et Fils. 1927). The direct influence upon fishes of sewage and of trade wastes containing organic matter or inorganic poisons, is discussed, and the methods used in treating the various pollutions on the Continent, in America, and in Great Britain are outlined. The report contains a comprehensive bibliography.

The disposal of noxious effluents is urgent in England, perhaps more so than on the Continent, where as a rule the towns have rivers carrying a greater quantity of water into which to discharge. As pointed out by Dr Redeke, the capacity of the rivers for self-purification allows the discharge of effluents up to a certain concentration without

material damage to the fisheries

Waste products containing organic matter, such as domestic sewage, the wastes from sugar beet, milk, or paper factories, abattoirs, etc., require treatment before reaching the rivers by allowing a natural fauna and flora of micro-organisms to act upon them for a sufficient length of time, usually under aerobic conditions, and the removal of solid matter, whereby their putrescibility is reduced. The problems of domestic sewage disposal have been solved on these lines in a very satisfactory manner on the whole; less attention has been paid to the analogous problems presented by trade wastes where, although similar methods are reported to give satisfactory effluents, the expense of installations or area of land required has militated against their general adoption

Trade wastes containing morganic poisons (gasworks, coke oven, artificial silk factory effluents) or inorganic poisons and organic matter (leather, paper, textile and glue trade effluents), each require particular treatment. Small volumes of highly polluting wastes can generally be got rid of by allowing them to seep through a sufficient amount of soil before entering any watercourse, but with large quantities the expense of treatment is the major problem.

In discussing to what extent pollutions will be injurious to fisheries, Dr. Redeke lays stress upon the extent to which an effluent will be diluted on entering a river, and concludes that the degree of purity of an effluent which should be aimed at depends upon such local circumstances; the discharge of substances directly poisonous to lower animals and plants should be prohibited, for these destroy the capacity of the stream for self-purification from organic wastes

### University and Educational Intelligence.

ABERYSTWYTH.—At a recent meeting of the Court of the University of Wales, it was announced that an anonymous donor has given a sum of £10,000 for the encouragement of research.

Cambridge —Mr J. A. Venn has been elected to a fellowship at Queens' College. H Barcroft, King's College, has been elected to the Michael Foster studentship in physiology.

Edinburgh —At the meeting of the University Court on July 18, a letter was received from Prof. J Cossar Ewart intimating his resignation from the chair of natural history. The Court accepted the intimation with very great regret, and expressed appreciation of the eminent services which Prof. Cossar Ewart has rendered to the University during his long and distinguished tenure of the chair, to which he was appointed in 1882.

On his retuement as physician to the Royal Infirmary Prof. G. Lovell Gulland intimated his resignation from the chair of medicine. The Court accepted the intimation with much regret, and resolved to record its grateful sense of the value to the University of Prof. Gulland's work as a teacher and physician.

The Court approved the terms of an ordinance founding the Buchanan chair of animal genetics, and directed that it be transmitted to the Privy Council and to the other Scottish universities. The foundation of this chair is part of the scheme for setting up a new and enlarged University Department of Re-search in Animal Breeding. The endowment consists of £20,000, half of which was contributed by Lord Woolavington, and half by the International Educa-tion Board of New York.

At a meeting of the Curators of Patronage of the

University on July 21, Prof. J. H. Ashworth, professor of zoology in the University, was unanimously appointed professor of natural history, as from Oct. 1, in succession to Prof. J. Cossar Ewart.

LONDON.—Dr. D. L. Mackinnon has been appointed as from Aug. 1 to the University chair of zoology tenable at King's College. Since 1919 Miss Mackinnon has been senior lecturer in zoology at King's College, and in 1921 the title of reader in zoology was conferred upon her. In addition to numerous papers in scientific journals, she has translated into English von Uexkull's "Theoretische Biologie" (Kegan Paul's International Library of Psychology, Philosophy, and Scientific Method, 1926), and has edited the translation from the Russian of Berg's "Nomogenesis" (Constable,

Prof. E. H. Kettle has been appointed as from October to the University chair of pathology tenable at St. Bartholomew's Hospital Medical College. Since

1924 Prof. Kettle has been professor of pathology and bacteriology in the Welsh National School of Medicine, Cardiff His published work includes the following. "The Pathology of Tumors" (Lewis and Co. 1st ed., 1916, 2nd ed., 1925) and numerous articles in the Journal of Pathology and Bacteriology, the Lancet,

and other medical journals.

Dr. Bronislaw Malinowski has been appointed as from August to the University chair of anthropology tenable at the London School of Economics. He has tenable at the London School of Economics. He has been University reader in social anthropology since 1923. He is the author of "Crime and Custom in Savage Society" (Kegan Paul, 1926); "Myth in Primitive Psychology" (Kegan Paul, 1926); "The Father in Primitive Psychology" (Kegan Paul, 1927); "Sex and Repression in Savage Society" (Kegan Paul, 1927); and of articles in "The Encyclopædia Britannica" (1926), "The Australia Encyclopædia" (1926), NATURE, Psyche, Zeitschrift für Volkernsuchalogie, and other journals Volkerpsychologie, and other journals
Dr W. H. Linnell has been appointed as from

Aug. 1 to the University readership in pharmaceutical chemistry tenable at the School of Pharmacy. From 1924 until 1926 Dr. Linnell was an organic research chemist at H.M. Fuel Research Station, and since October 1926 he has been lecturer in pharmaceutical chemistry and Director of the Chemical Research Laboratories in the School of Pharmacy.

OXFORD.—The following elections to University scholarships on the Theodore Williams foundation have been made: F. M. Trefusis, Exeter College, and M. W. C. Oldfield, University College, in human anatomy; Joyce Wright, Somerville College and J. G. anatomy; Joyce wright, somerville College and J. G. Reid, University College, in pathology, A. L. Jacops, Jesus College, and A. W. D. Leishman, University College, in physiology. Mr. Robert Pakenham-Walsh, of University College, has been awarded the Welsh prize for excellence in anatomical drawing.

Dr. Harlow Shapley of Harvard College Observatory, Cambridge, Mass., has been appointed to deliver the Halley Lecture in 1928.

Two useful educational bibliographies have reached us from the United States Bureau of Education: a classified list of publications of the Bureau of special interest to secondary school teachers, and a record (Bulletin, No. 2, 1927) of current educational publications. The latter is a fifty-eight-page pamphlet comprising some six hundred titles classified and annotated.

THE New Education Fellowship is holding its fourth international conference at Locarno on Aug. 3–15, the general theme being "The True Meaning of Freedom in Education." In the list of speakers appear the names of the following, among others: Prof. Pierre Bovet, Director of the International Bureau of Education, Geneva; Mrs. Beatrice Ensor and Dr. Elisabeth Rotten, Directors of the New Education Fellowship; Dr. Alfred Adler, founder of the School of Individual Psychology, Vienna; Prof. Carson Ryan, of Swarthmore College, U.S.A., President of the National Vocational Guidance Association; Dr. Carleton Washburne, Superintendent of Schools, Winnetka, U.S.A.; Sir Jagadis C. Bose; Prof. O. Decroly of Brussels, originator of the Decroly method; Dr. Adolphe Ferrière, founder of the International Bureau of New Schools; M. P. Otlet; and Mme. Guérntte, of La Nouvelle Education. Bedales, Frensham Heights, and other pioneer schools are to be represented. There will be an exhibition of children's work and auto-didactic material. The headquarters of the Fellowship are at 11 Tavistock Square, London, W.C.1.

## Calendar of Discovery and Invention.

July 31, 1846.—In 1840, Lord Armstrong, then a lawyer thirty years of age, in a letter to the Mechanics' Magazine, directed attention to the advantage of water under pressure as a mechanical agent and a Six years later he erected a reservoir of power crane on the quay at Newcastle which was worked by water power, and on July 31, 1846, took out a patent for an "apparatus for litting, lowering and hauling." This was the beginning of the present extended use of hydraulic pressure for cranes, capstans, lifts, gun machinery, and machine tools To develop his machinery, Armstrong in 1847 joined the small engmeering firm of Donkin, Cruddas, Potter, and Lambert, of Elswick, and from this sprang the worldfamous engineering works on the Tyne.

August 1, 1774—Oxygen was discovered independently by Priestley and by Scheele, Priestley's famous experiment with the red oxide of mercury being made on Aug 1, 1774. The new gas, thought by Priestley to be common air deprived of its 'phlogiston,' was called by him 'dephlogisticated air,' and it was Lavoisier who named it oxygen.

August 3, 1677.—One of the earliest scientific academies was that founded in Germany in 1652 and on Aug. 3, 1677, given the title "Sacri Romani Imperii Academia Naturae Curiosorum" by the Emperor Leopold I. The inauguration of this society was stimulated by the writings of Bacon, and it is known to-day as the "Leopoldinish-Carlonische Deutsche Akademie der Naturforscher" of Halle.

August 4, 1877.—Many inventors have contributed to the improvement of internal combustion engines, but the greatest single improvement was that made just fifty years ago by the German engineer, Nicolus Otto (1832–1891), who on Aug. 4, 1877, took out the German patent for the well-known four-stroke cycle of operations. Lenour and Hugon had produced the first practical gas engines, and these had been superseded by the engine invented by Otto and Langen in 1866. All these, however, were far inferior to the new type of Otto, who introduced the plan of compressing the explosive mixture in the working cylinder as proposed by Barnett in 1838.

August 4, 1894.—The exploration of the upper atmosphere by means of self-registering instruments lifted by kites was initiated by Abbott Lawrence Rotch (1861-1912), whose first experiments were made on Aug. 4, 1894. Rotch was the founder of the meteorological observatory at Blue Hill, Hyde Park, Mass., 635 feet above sea-level

August 5, 1816.—Among the pioneers of the electric telegraph was Sir Francis Ronalds who, before the invention of the voltaic battery and the discoveries of Oersted, in 1816 laid down some miles of wire in his garden at 26 Upper Mall, Hammersmith, and transmitted charges by means of friction machines. His offer of a demonstration led to the Admiralty official reply, dated August 5, 1816, "That telegraphs of any kind are now totally unnecessary, and that no other than the one in use [the semaphore] will be adopted.'

August 6, 1812.—Regular steamboat traffic in Europe began with Henry Bell's Comet, launched on July 24, 1812, which began her trips on Aug. 6. Glasgow Herald of Aug 10 contained the following paragraph: "We understand that a beautiful and commodious boat has been just finished, constructed to go by wind, power and steam, for carrying passengers on the Clyde between Glasgow, Port Glasgow, Greenock, and Gourock. On Thursday it arrived at the Broomielaw in three hours and a half from Port Glasgow.'

### Societies and Academies.

#### LONDON

Optical Society, June 9.—T H. Harrison The use of photo-electric cells for the photometry of electric lamps. A description is given of apparatus and experiments designed for giving the highest accuracy and precision in the photometry, using photo-electric cells, of electric lamps Although the methods adopted are not novel, yet every care has been taken to obtain the highest sensitivity in the photo-electric current measuring apparatus and to maintain the lamps at a steady, accurately known voltage. It is claimed, therefore, that the results are useful in showing the maximum capabilities of photo-electric cells when used in the usual manner with a sensitive electrometer or electroscope Sources of error and their elimination and the computation of the accuracy of the results are discussed -R Kingslake perimental study of the best minimum wave-length A special telescope is defor visual achromatism scribed, in which the chromatic aberration can be varied continuously without introducing any other undesirable aberrations. By the aid of this apparatus, many determinations have been made as to the best type of achromatism for visual observations, in daylight, in artificial light, and on astronomical objects Several observers were employed to make settings, and their opinions as to the most desirable type of achromatism are tabulated and compared In general it is found that a moderate amount of undercorrection is required to give a truly colour-free image, that less undercorrection is needed if the best definition is to be obtained, and that a slight overcorrection is desirable for astronomical work—S. K Datta: On Brewster's bands (Part ii.). The nature of the patterns obtained by the superposition of two systems of Haidinger's rings when the actual law of spacing of the rings is considered is discussed.

Mineralogical Society, June 14.—A. F Hallimond: On the atomic volume relations in certain isomorphous series. For isomorphous salts of the eutropic elements potassium, rubidium. cæsium, the differences cæsiumpotassium and rubidium-potassium stand in constant ratio, and the same ratio holds good for the free metals, though these are considerably larger than in the combined state, the constancy does not extend to the salts of ammonium or thallium. A modified additive relation is indicated, the volumes of the metals when free and when combined being in the same ratio as the differences for the free metals and for the respective isomorphous series. This would appear to be a distinctive character of each 'eutropic' group of elements.—P. K. Ghosh · Petrology of the Bodmin Moor grante (eastern part), Cornwall. Three types of granite are mapped and described in detail . (1) an earlier coarse-grained 'normal granite,' followed by (2) a coarse-grained granite of Godaver type, and (3) a fine-grained granite. Various minor intrusions connected with these are described, and also their altered faces. Several types of hornfelsed inclusions of sedimentary rocks are distinguished —P. G. H. Boswell: On the distribution of purple zircon in British sedimentary rocks. The properties and behaviour under radioactive treatment of purple zircon from sedimentary rocks are described The mineral occurs at practically every horizon in British sedimentary rocks. In the Carboniferous, Permian, Triassic, and Aptian rocks it is especially abundant, and is there associated with numerous other minerals apparently freshly derived from crystalline metamorphic rocks. —J. Drugman: On  $\beta$ -quartz twins from Cornwall.

3-quartz seems to be sufficiently differentiated from a- or low-temperature quartz for the two to be treated quite apart from each other. This is specially the case with the twin-laws one observes in these 3-quartz, twinning with inclined axes is a very comabundant in the Cornish localities at Belowda Beacon, a china-clay pit near Belowda Beacon and Wheal Coates. Besides twinning on (1011), Estérel twinning, and twinning on (1122), three new laws are stated, namely, twinning on (3032), confirmed by a good Estérel specimen; twinning on (2021) (and perhaps on the Zinnwald law) and lastly twinning on (2132), This latter also confirmed by an Estérel specimen is, however, probably of extremely rate occurrence

—E. V. Holt and H. F. Harwood: The separation of
manganese in rock analysis. The whole of the manganese can be completely precipitated with the alumina and ferric oxide. The solution after removal of silica is diluted to 400 cc, heated to boiling after the addition of ammonium chloride, and ammonia added to alkalinity. Bromine water is then run in very slowly from a tap funnel, small additional quantities of ammona being simultaneously added to keep the solution alkaline When the addiadded to keep the solution alkaline tion of the bromine is complete the liquid is boiled for one minute and then filtered. The precipitate is redissolved and the precipitation repeated; in the combined filtrates lime and magnesia are determined by the usual methods The results are perfectly satisfactory up to a limit of 50 mgm MnO; when more than that quantity is present, some lime and magnesia are liable to be carried down with the alumina precipitate, but such a case will practically never occur in rock analysis.—L J. Spencer: Corundum twins from Transvaal. Large twinned crystals of corundum, up to 6 inches across but only about an eighth of an inch thick, are abundant in plumasite rock near Bandoher Kop, northern Transvaal twin-plane is a face of the primary rhombohedron and the twinned crystals have a form resembling arrow-heads.

Royal Meteorological Society, June 15.—J. Edmund Clark, I D. Margary, and R. Marshall: Report on the phenological observations in the British Isles, December 1925 to November 1926. 373 sets of records were received, but observers would be welcomed in the western halves of Ireland and Scotland, and all Scotland north of Inverness. The five weeks' cold spell preceding Christmas 1925 retarded the first indications of the new season's growth, but this was quickly neutralised by warmth equally abnormal, culminating in the closing week of winter and continued on to Easter. In consequence flower, bird, and insect records were very early up to mid-April, notable being those of the arrival of cuckoo and swallow and flowering of hawthorn. Then everything was retarded by a long spell of cold, worst about mid-May, injuring the fruit crop, particularly apples. June was cool and very dry and in many parts July brought a deluge. Field crops were helped by a dry summer and fairly warm August, warm September and early October. Grain expectations failed of full realisation upon threshing. Destructive mid-October frosts damaged late potatoes and practically wiped out autumn colouring. Many records were obtained of the return after this of swallows and housemartins, often lingering all through November and in some cases into December.—G. C. Simpson: Past climates The paper discusses from the meteorological point of view the possible changes in climate which can be brought about by changes in the physical condition of the earth's surface—chiefly changes in the extent and distribution of the land masses and changes in their height-unaccompanied by any variation in solar The zonal distribution of temperature has not materially changed; there must always have been a cold polar zone, a warm tropical zone, and an intermediate temperate zone, all very similar to those which exist to-day. Further, a detailed examination of the existing variations in mean annual temperature along various circles of latitude leads to the conclusion that no rearrangement of land and water could have produced larger variations of mean annual temperature than are to be found in the northern hemisphere to-day. The ice sheet which covered northwest Europe during the last great ice-age could not have been caused by the elevation of Scandinavia The present conditions in tropical regions, where in the coldest parts the snow-line is to-day more than 5000 metres above sea-level, lead to the conclusion that ice could never reach sea-level within the tropics.

#### Dublin

Royal Irish Academy, June 27 -H. Ryan and V Coyle: The hydrolysis of n-butyl nitrate. n-Butyl nitrate, formed by the action of nitric and sulphuric acids on n-butyl alcohol, reacted very slowly with cold aqueous or alcoholic potash With a warm solution of potash the ester was, unlike those of the polyhydric alcohols, readily converted into butyl alcohol and potassium nitrate. In addition to these bodies, potassium nitrite and a resin were formed. Alcoholic ammonia had little action on the nitrate, but in the presence of sulphuretted hydrogen, butyl alcohol was formed very readily.—H. Ryan, J. Keane, and J. C. McGahon. On 3-nitrodiphenylene oxide. Two mononitro derivatives of diphenylene oxide are known. One of these melts at 182° C. and the other at 110° C, and each in turn has been assumed to be 3-nitrodiphenylene oxide. It is now shown that the latter body is a new mononitro-diphenylene oxide melting at 141°C, which is obtained by diazotisation of 2-amino-4-nitrodiphenyl ether, followed by elimination of nitrogen with formation of the diphenylene oxide grouping —Joseph Doyle and Phyllis Clinch. Seasonal changes in conifer leaves, with special reference to enzymes and starch formation. The absence of starch from evergreen leaves in winter is largely due to an internal change which necessitates, irrespective of temperature, a great increase in sugar concentration before starch synthesis begins. This has to be related to corresponding changes in the carbohydrate enzymes. Although invertase is always present. maltase, dextrinase, and amylase may be absent or much less active in winter. Starch may develop in the absence of maltase and dextrinase; and, in some cases, independently of assimilation, light may be necessary for its formation in winter. Osmic acid staining substances are very plentiful, but they are not fat, which is sparingly present if at all. Lipase is not detectable at any season.

### PARIS.

Academy of Sciences, June 20.—G. André and E. Demoussy The distribution of potassium and sodium in plants. From the experimental facts given, it follows that the distribution of potassium and sodium, considering only the soluble forms, is dependent on diffusion. During the growth of the plant the most mobile element, the potassium, travels farthest from the mixed solution. After the period of growth the ratio potassium/sodium tends to fall.—P. Viala and P. Marsais: A new disease of grapes (seleriasis), due to Sordaria uvicola. Details of mode of growth and effects of this fungus are given, which at present is confined to Bessarabia.—Pierre Bazy:

Remarks on the note by M. Raymond Hamet. protest against the conclusion that in cases of syncone under chloroform or other anæsthetics the injection of adrenalme may be harmful. The author contends that the value of the adrenaline injection in tends that the value of the adrenalme injection in such cases is well proved — Riquier — The general integration of the partial differential equation s=f(x, y, z, p, q) — Charles Camichel — The vortices provoked by an obstacle immersed in a flowing liquid. A résumé of experiments made by the author in collaboration with Dupm, Escande, and Teissié Solier — Amé Pictet and H. Vogel: The synthesis of maltose — René Maire and Paul de Peyerimhoff The discovery of Pinus nigra in the north of Africa This pine has not hitherto been met with in Africa. The age and position of the trees exclude the possibility of introduction from Europe during French occupation -Charles Fabry was elected a member of the section of general physics in succession to the late Daniel Berthelot, and Alexis Carrel a corres-Pondant for the section of medicine and surgery.

Otakar Borůvka The projective geometry of the analytical correspondences between two planes. Gaston Julia · Remarks on the singular right lines of congruences.—J. Hjelmslev The invariants of integral series—André Roussel: An intermediate method of the calculus of variations.—(1. Pólya: Integral functions with lacunar series -Gr. Fichtenholz. Suites of analytical functions — Biernacki: The displacement of the zeros of integral functions by their derivation.—Kiveliovitch. The periodic orbits of the problem of three bodies with impacts of two bodies.—P. Fatou · The movement of the nodes of certain orbits.—Emile Belot: The origin and values of the eccentricities of the orbits according to the dualist cosmogony -L. Rosenfeld: The magnetic electron and wave mechanics -V Posejpal: The yield of fluorescence of the K level for the Ka lines. -R. Descamps. The natural rotatory dispersion, in the range of the ultra-violet spectrum, of four aqueous solutions of tartaric acid Beauvais and Mesny: An arrangement of the Faraday cage for radio-telegraphy.—Mlle St. Maracineanu: Researches on the radioactivity of matter after long exposure to solar radiation. In a previous communication it has been shown that a leaden roof, which had been exposed for a long period to solar radiation, showed distinct radioactivity. That this lead was not originally radioactive has now been proved by cutting out a piece of the lead (2 mm thick) and examining t in the laboratory. Only the exposed face was found to be active, the radioactivity on the under side being nil. The possibility that the radioactivity found was due to radioactive deposits from the atmosphere was disproved. Zinc and copper from the same roof also showed radioactivity, but less than the lead .- H Deslandres . Remarks on the preceding communication. The importance of these results is emphasised and the necessity for additional research indicated. The facts at present known would appear to be best explained as being due to a special action of the sunlight .- H. Jedrzejowski . The charge of the a-rays emitted per second by 1 gram of radium. The method used was based on that of Rutherford and Geiger; with some additional refinements. The charge emitted by 1 gm. of radium was found to be 33.4 electrostatic units per second, corresponding to the number of a-particles  $N=3\cdot 50\times 10^{10}$  This is if good agreement with recent results of H. Geiger and A. Werner, of J. Thibaud and of L. Moitner, but is appreciably lower than the  $3.72 \times 10^{10}$  found by V. F. Hess and R. W. Lawson —A. Andant and E. Rousseau: The photolysis of hydrocyanic acid by the total radiations and by the filtered radiations of

the mercury arc The data given show that photolysis by ultra-violet light is hindered by the presence of radiations of longer wave-length—Eugene Cornec and Joseph Dickely · Studies on sodium perchlorate—Victor Tombard: The permeability of iron and of platinum to hydrogen The permeability of iron to hydrogen at a given temperature is proportional to the square root of the pressure. At constant pressure and varying temperature, the permeability of iron and and varying temperature, the permeaninty of iron and platinum to hydrogen, like that of nickel, is of the form  $d = a^t$  (a, constant; t, temperature).—Amand Valeur and Paul Gailliot: The passage from trimethylarsine to cacodylic acid. Trimethylarsine is converted into the dichloride by the direct action of chlorine; at 180° C. this gives methyl chloride and cacodylic ablanda and the letter is quantitatively. cacodyl chloride, and the latter is quantitatively oxidised to cacodylic acid by means of hydrogen peroxide.—Charles Prévost: An unexpected reaction of the di-isocrotyl dibromides -Marcel Bouis . The addition of hydrobromic acid to the allene hydrocarbons.—Paul Gaubert. Helicoidal building up in crystals.—Louis Barrabé. The Jurassic and Cretaceous sedimentary series of the western coast of Madagascar, between Manambolo and Manambao.— F. Blondel. The recent volcame action in the southeast of Indo-China The magnitude of the volcanic area is remarkable, but owing to the deep changes in the basalts and the absence of sedimentary strata, the exact date of the eruptions cannot be determined with accuracy.-J. MacLaughlin · Measurements on the large ions at Paris.—Ch. Maurain: Magnetic measurements in Alsace and Lorraine —Henri Coupin: The carbon nutrition of Penicillium glaucum by means of various organic compounds of the fatty series Out of 47 organic substances added to an morganic culture medium, Penicillium can use carbon from 22 of them, including ethyl alcohol, glycerol (but not glycol), sugars, malic and succinic acids -Denis Bach: The nitrogen nutrition of the Mucorineæ. The assimilation of the nitric ion.—Robert Lami: The influence of a peptone on the germination of some Vanda.—Jean Bathellier. The fungus cultures made by the Indo-Chinese ants—Ch. Brioux and J. Pien: The lime requirements of acid soils. The slow reappearance of acidity after saturation with lime.—Jacques Pellegrin: The barbel of with lime.—Jacques Pellegrin: Morocco.-H. Joyet-Lavergne: The relations between glutathrone and the chondriome. Some results obtained by the use of sodium nitroprusside as a histological reagent for glutathione.—Philippe Fabre: The shunt shock on the gastrocnemius of the frog.-Joseph Thomas: Injections of cancerous autolysates m the treatment of cancer.—Marcel Duval and P. Portier: The total carbon choxide content of the blood of freshwater invertebrates and marine invertebrates. The blood of freshwater invertebrates is richer in carbon dioxide than that of marine mvertebrates. No reason can be assigned for this difference.—R. Fosse and A. Hieulle: The identification of allantoic acid in the leaves of *Acer pseudo*platanus.-H. Cardot, J. Régnier, D Santenoise and P. Varé: The variations of the cortical excitability, in relation with the pneumogastric excitability, the thyroid apparatus and the muscular activity.—H. Simonnet and G. Tanret: The hypoglycæmic properties of galegine sulphate.—J. Cantacuzène and O. Bonciu: The agglutinability acquired on contact of scarlatma filtrates by bacteria heated to 60° C .--X. Chahovitch and Mile. Vichnitch: The energy metabolism in the course of experimental tuberculosis.

### ROME.

Royal National Academy of the Lincei, April 24.— L. Tonelli: A property of integrable functions.—

G. Armellini . Selective absorption of the terrestrial atmosphere and the effective and apparent stellar temperature The effect produced on the spectrum of a star by the selective absorption of the earth's atmosphere is to render the distribution of energy in the stellar spectrum such as would be obtained from the radiation of a black body at a temperature different from, and lower than, the effective temperature of the star. The difference between the two temperatures is proportional to the selective atmospheric constant and to the square of the effective temperature.—A. Lo Surdo The electric current filtered through a saturated thermionic valve If a saturated thermionic valve is inserted in a circuit with the object of filtering the current due to a pulsating electromotive force, the pulsations of the current are greatly attenuated but cannot be entirely eliminated—L. Rolla and G. Piccardi. Electro-affinity potential of molybdic anhydride Measurements made by the molybdic anhydride flame method give the value 2.73 volts for the electronic affinity potential of molybdic anhydride rendered free from bases by sublimation. This result is calculated on the assumption that, at the flame temperature employed, namely, about 1970° absolute, the anhydride undergoes no appreciable dissociation. —S Franchi Geology of the northern Appennines.—R. Calapso: A transformation of the rectilinear congruences W.—S Cherubino: The surface integrals of quadratic differential forms—S Bernstein: New demonstration of an inequality relating to trigonometrical polynomials —O Onicescu: Geodetic displacement, stability, and Whittaker's problem.—A. Rosenblatt: Kutta-Joukowski's theorem.—E. Fermi and F. Rasetti. Measurement of the ratio h/k by means of the anomalous dispersion of thallium —U. Sborgi: Anodic behaviour of metals in non-aqueous solutions. Comparison of the results obtained on electrolysing sodium and ammonium chlorides, and ammonium nitrate in aqueous and in ethyl alcoholic solutions indicates that, to a large extent, the anodic behaviour of metals is similar in aqueous and nonaqueous solutions.—G. Malquori: The systems  $AlCl_3$ —HCl— $H_2O$ , KCl—HCl— $H_2O$ , and  $KNO_3$ — $HNO_3$ — $H_2O$  at  $25^\circ$  (in.). The solubilities of alumnum and potassium chlorides in water are diminished by the presence of hydrochloric acid. On the other hand, potassium nitrate is increased in solubility by addition of nitric acid to the aqueous solution; aluminium nitrate, however, follows the general rule.-C. Fontana: Identity of the crystalline structures of Fe $_3$ S $_4$  and FeS. The results of X-ray analysis show that the interaction of magnetite and hydrogen sulphide under the ordinary pressure at 1000° is expressed by the equation:

 $\text{Fe}_2\text{O}_3$ .  $\text{FeO} + 4\text{H}_2\text{S} \longrightarrow 3\text{FeS} + \text{S} + 4\text{H}_2\text{O}$ .

The sulphur does not occupy a fixed, characteristic position in the crystal lattice, and the existence in the product of the reaction of the compound Fe<sub>3</sub>S<sub>4</sub> as a chemical individual cannot be regarded as proved-A. Ferrari: Crystalline structure of iodine. Investigation by Laue's method, in conjunction with the rotating crystal method, shows that iodine exhibits a rhombic lattice, the elementary cell of which consists of an orthogonal parallelepiped containing eight atoms and having the dimensions a = 4.760 Å U.; b = 7.164 Å.U.; and c = 9.783 Å.U.—D. Bigiavi. Action of peracetic acid on the acetyl derivatives of aromatic amines. The action of peracetic acid on aromatic amines yields the corresponding nitrocompounds, together with the azoxy-compounds. but similar treatment of the acetyl derivatives of the ammes gives the nitro-compounds alone.-G. Natta: Crystalline structure of the chlorides of tervalent metals (1.). Chromic chloride. This salt crystallises in the rhombohedric system and probably in the holohedral class, its elementary cell containing one molecule of CrCl, and having the side a = 4.42 Å.U. and the axial ratio c: a=1 29-1 30. The calculated density is 2.71—C. Perrier: Two recent notes by Philibert. The apparent biaxiality which may occur with Iceland spar when observed with the help of Federow's plate does not detract from the value of this plate when the segments are properly mounted. D Cattaneo: Ultramicroscopy of the crystalline lens (i.). The ultramicroscopic character of the lens (1.). normal crystalline lens. Ultramicroscopic investigation confirms Bottazzi's view that the protoplasm of the crystalline lens consists essentially of optically homogeneous material, but shows also that the crystalline fibres may contain a phase differing optically from such homogeneous material.

### British Woodlands.

THE seventh Annual Report of the Forestry Commissioners 1 recently issued summarises the work which has been accomplished in Great Britain up to Sept. 30, 1926. Interesting data are given of a census of the woodlands of Britain undertaken with commendable persistence by the Commissioners. This census has shown that the existing woods amount to 2,958,630 acres, less than half of which can be considered productive latter fact appears to have come as a surprise to the Commissioners. The few experts having a knowledge of the forestry conditions of Great Britain could have foretold the result with considerable certainty, and probably not a few of the proprietors also, in the absence of any expert knowledge to guide them

It was common knowledge that considerable areas were maintained as game coverts, questions of their value for timber production being entirely subordinated to the premier object. The late Sir William Schlich often directed attention to this fact during the forty years he advocated an afforestation campaign in Britain. The heavy fellings made in the utilisable coniferous areas during the War have admittedly intensified the need for an afforestation programme, but have scarcely changed it. The question still remains one upon which the Government and public, but chiefly the latter, must definitely make up their minds. The problem is a pressing one, but the costs of afforestating the several million acres which the experts are unanimous in admitting can be made more productive under trees will be very much higher than would have been the case had the work been done before the War. The present sanctioned programme comes to an end in 1929, and the Commissioners, in the report under review, express anxiety as to the continuance of the work and advise that it should be carried out on an enhanced scale. The report, in fact, is far more than a mere enumeration of the work of the year. It is more concerned with placing before its readers the work achieved to date and the lines upon which, in the view of the Commissioners, the next ten-vear programme should be drawn.

The arguments for and against the enhancement of the afforestation programme are weighty; for the true interests of the country, economic and otherwise, support the plea of the Commissioners for an enhanced programme. Those against are

<sup>1</sup> Forestry Commission. Seventh Annual Report of the Forestry Commissioners, Year ending September 30th, 1926. Pp. 45. (London: H M. Stationery Office 1927.) 1s. net.

chiefly concerned with the great expense involved, and the added factor that an experienced forest service has vet to be built up. After the wars of a century ago, prices remained high for a considerable period and gradually dropped. It may be hoped that the future, how distant none would dare to say, will see a similar reduction. This would mean that plantations now being made at £5:16s. to £7:10s. an acre might cost only half the amount. The cost of buildings, etc., for small-holdings would likewise be reduced; and so forth throughout all the various branches of forest work. Up to Sept. 30, 1926, 186 small-holdings (the average cost of 63 new buildings during 1926 was £623 apiece) had been completed. It is hoped that 750 small-holdings will be completed or in process of establishment (the limit in sanctioned cost is £800 apiece) by the end of 1929. It is stated that their number could be increased to 3000 or 4000 in the next ten-year period. The Commissioners admit that they have only had two and a half years' experience of this Experts in Great form of rural settlement. Britain disagree as to whether such a form of settlement is practicable. It is a common method in France; but small-holders there work 10 hours a day as a minimum during the spring and summer and are far thriftier than our people

The cost of 'planting' is shown in a curious way in the Report. All expenses during the first year of formation, including weeding, are termed the cost of 'planting.' If 50 per cent. of the plants fail and have to be replaced, this operation is shown under 'establishment' of the plantation. Presumably if the whole of the trees under 'planting 'failed, the replanting of the plantation would be shown under 'establishment,' a somewhat complex puzzle to set the forest officer in charge, say, fifty years hence. The Report shows (Table E 5) that during the seven years £132,767 were spent on planting and £35,061 on 'beating up,' i.e. replacing failures in the plantations. This amounts to something more than 25 per cent. failures in the first plantings. For 1926 the figures are £28,621 and £13,071, slightly less than 50 per cent. failures. No private proprietor could afford to plant if 'beating up' on this scale had to be faced. It is scarcely a justification for speeding up the planting campaign during the next ten years, which is so warmly advocated in the Report.

That much good work has been accomplished by the hard-working officers of the young service under the Forestry Commissioners is undeniable. That experience can only come with increased knowledge and practice is equally undeniable.

### Modern Alchemy.

Atomzertrummerung: Verwandlung der Elemente durch Bestrahlung mit o-Teilchen. Von Hans Pettersson und Gerhard Kirsch. Pp. viii + 247. (Leipzig: Akademische Verlagsgesellschaft m.b.H, 1926.) np.

THE artificial disruption of many of the chemical elements can be regarded as a direct outcome of the study by Geiger and Marsden of the scattering of a-particles by matter, and the formulation, in 1911, of the nuclear theory of the atom by Sir Ernest Rutherford. Theoretical work of Darwin on collisions of a-particles with the nuclei of atoms was supplemented by the experimental work of Marsden and Lantsberry, who discovered the production of H-rays in hydrogen when a-particles collide with the nuclei of hydrogen atoms. The later development of this work by Sir Ernest Rutherford revealed the production of H-rays when nitrogen is bombarded by a-particles, and in this we have the first instance of the artificial disintegration of an element by a-rays.

Since 1919, the subject has been actively pursued by Rutherford and Chadwick in the Cavendish Laboratory at Cambridge, and the ejection of H-particles from the nuclei of many of the lighter elements has been established, the effects being most marked for elements of odd atomic number. Unfortunately, experiments of this nature require the use of appreciable quantities of radium, and this undoubtedly accounts for the fact that so fascinating a study has not been taken up in many more laboratories. In 1922, however, the authors of the present monograph commenced work on similar lines at the Vienna Radium Institute, which, since it was opened in 1910, has been an active centre of radioactive research, and possesses ideal facilities for such work. During the last five years these workers have gathered together a band of enthusiastic researchers, who have made valuable contributions to the subject under consideration.

As a result of the investigations carried out at Cambridge and Vienna, our knowledge of the effects of a-bombardment of the elements has reached a state which justifies the appearance of a monograph of the type under review. In writing it, the authors' aim was to arouse the interest of physicists in this fascinating branch of research, and to stimulate others to take an active part it its development. But, alas, the lack of strong radioactive preparations is a real difficulty. To those who are more fortunately placed in this respect, however, the book will be found of great

value in making readily accessible not only the experimental methods and results, but also their interpretation. The number of substances so far investigated is relatively small, and the methods of attack used at Cambridge differ in many respects from those used at Vienna. In consequence, the results obtained in the two laboratories are not always directly comparable, and in some respects show lack of agreement. Nevertheless, the authors have endeavoured to be impartial in their treatment, and science owes them a debt of gratitude for presenting such an excellent review of the subject.

In the opening chapter the question of transmutation in general is treated historically, and the authors wisely refram from a discussion of recent claims in this field. We are then introduced to the main properties of a- and H-rays, and pass in review the relevant theory and the experiments carried out to test the validity of the nuclear theory 'of the atom. Chapter iii. deals with the earlier experiments on atomic disruption carried out at Cambridge and Vienna, and discusses the results of investigations on the \alpha-particles of long range emitted by the C-products of radium and thorium. By the introduction of the method of observation of the atomic fragments in a direction perpendicular to that of the bombarding a-particles, it became possible to count scintillations much nearer the source of disruption, for both the number and range of the scattered a-particles are greatly reduced in this way. This method has been successfully applied both at Cambridge and Vienna, and the various results are given in the same chapter. The results of observations in the backward direction by the 'retrograde' method are also described This method has been extensively used at Vienna and permits of a still closer approach of the counting screen to the material under examination. more recent investigations on collisions with the nuclei of atoms are reviewed in Chapter iv.

Since the intensity of the scintillations produced by a-particles falls off considerably near the end of the range and the brightness of H-scintillations is much less than that of scintillations due to normal a-particles, the correct allocation of feeble scintillations is often a matter of difficulty. Pettersson and his co-workers have developed the technique of identification by direct comparison of a- and H-scintillations, and this is described in Chapter v., where an interesting account of the photographic action and absorption of H-particles is also given. This chapter also contains a description of Stetter's ingenious adaptation of the mass-spectrograph, by means of which the value e/m =

9560 ± 300 was found for the H-particles from paraffin wax. Chapter vi. is devoted to the various unsuccessful attempts which have been made from time to time to influence the rate of decay of radioactive substances, whilst the following chapter deals with various theoretical considerations on such topics as nuclear collisions and the size of the nucleus. For any one contemplating work on the subjects of this volume, Chapter vin. is a veritable mine of useful information It contains most valuable details on the preparation of sources of radiation, the application of the scintillation method, the optical devices used in work on disruption, the preparation and calibration of absorption screens, and other matters of technique. The book closes with an interesting chronological review of the work on atomic disruption, and a complete list of the relevant references to the literature.

From the results of the Vienna workers, the phenomenon of disruption by a-particles would appear to be of much more general applicability than the Cambridge results indicate. Moreover, whereas the latter school finds that disruption is not effected by a-particles of smaller range than about 4.9 cm., the former claims to have obtained positive results with a-particles of range less than 4 cm. (e.g. with polonium). The yield of H-particles found in Vienna is also considerably greater than that found at Cambridge. Such discrepancies do not appear surprising when we consider the great strain associated with the counting of such feeble scintillations as those produced by H-particles, so clearly revealed on p. 225 of the book under review.

It is unfortunate that observations have usually been made on the side of the scintillation screen remote from the zinc sulphide surface, as this must involve a distinct diminution in the brightness of the flashes, and render counting more difficult and less certain. Naturally, both schools have great faith in their own results, and whilst Kirsch and Pettersson have obtained evidence that the observed differences are attributable to the different optical arrangements used, Chadwick has directed attention to the difficulty of ensuring the absence of scattered a-particles of low velocity in experiments at short range. In our opinion, the position of the Viennese workers has been greatly strengthened by their more recent confirmatory evidence obtained by other methods, and it is to be hoped that before the appearance of a second edition of this valuable book the existing discrepancies will have been satisfactorily removed, and the main features of this fascinating subject firmly R. W. L. established.

# The Breeding and Rearing of Farm Animals.

Breeding and Improvement of Farm Animals By Prof. Victor Arthur Rice. (McGraw-Hill Publications in the Agricultural and Botanical Sciences.) Pp. xiv + 362 (New York. McGraw-Hill Book Co, Inc.; London: McGraw-Hill Publishing Co., Ltd., 1926.) 17s. 6d net.

T is becoming more and more realised that it is a matter of primary importance to the stockbreeding industry to possess an understanding of the processes of reproduction and development. Of our existing knowledge of this subject in its relation to the breeding of farm animals, some was acquired long since by direct practical experience and has been handed down for countless generations. It follows that such knowledge, although generally sound-for otherwise it could scarcely have stood the test of time-was necessarily limited and uncorrelated, for it existed without reference to scientific system and is not founded on scientific principles. In recent years, however, a great deal of attention has been paid to the science of breeding, and although it cannot be said that research methods have led as yet to any spectacular developments of economic importance, nevertheless a great number of observations have been made and deductions arrived at which in the aggregate are already having an important effect upon practice.

The present volume has been written as a text-book on the breeding and rearing of farm animals. While it is in many respects severely practical, the author has succeeded in giving it a definite scientific bias, and much of the recently acquired knowledge which has been won by physiological and genetic investigation is duly included. Moreover, by giving a connected account of the different departments of the subject, the author points the way to further progress in the improvement of the various classes of stock.

The opening chapter, among other matters, deals with the derivation and history of the domestic animals, and the author, in common with other writers, takes the view that most of the species have had a multiple origin, but Prof. Ewart's extended researches on this subject are not alluded to. Chapter ii is on the physical basis of inheritance, and the chromosome theory is adequately described. Here the author definitely identifies the genes or factors with the 'beads' which comprise the chromosomes. In a later chapter he goes even further and suggests that the genes are either proteins or enzymes (or both), merely making the

reservation that "it is not known" which of the alternatives is true. Such a statement is much too crude for a scientific text-book, and we fail to see what advantage is gained, in the present state of knowledge, for any theory of heredity by identifying the mechanisms of transmission with definite chemical compounds or agencies.

The third and fourth chapters contain useful descriptions of the male and female genital organs. and the processes which occur in them, but the almost complete absence of any account of the cestrous cycle is a strange omission in a text-book on animal breeding. Such information as is given is confused and contradictory. Thus, the author quotes Williams as saying that "if a cow is bred during a heat period and does not conceive she will subsequently menstruate, while if she does conceive she will not menstruate" Here Wilhams's reference to 'menstruation' was clearly intended to refer to the sanguineous discharge which sometimes takes place shortly after cestrus and really represents the termination of the preceding cestrous cycle. Prof. Rice, however, in the very next sentence proceeds to state that "the menstrual period lasts for about 24 to 48 hours in cattle," etc. and that "this is a most important season, because it is apparently only during this time . . . that a mare, cow, ewe, or sow can be successfully impregnated." The use of the term 'menstruation' as synonymous with cestrus is quite unjustified

In the next chapter, on fertility, there is some further allusion to the estrous periods (p. 54), but the distinction between the monestrous and polycestrous conditions is not drawn and there is no reference whatever to the short (diæstrous) cycle either in pigs or sheep. This is also omitted in the summary of the "Chronological Order of Reproductive Processes" (p. 47), where we find a further confused statement as to menstruation (in cattle). Again, it is not correct to describe the absorption of the corpus luteum as occurring at a later stage of the cycle than "nutrition of young." It is a mistake also to describe the vasa deferentia as the homologues of the Fallopian tubes, as these have a different origin in embryonic development. There is an interesting description of the American work on the vitality of the ova and the spermatozoa, but no account is given of Hammond's more extended investigations published in 1925, and the author does not appear to realise the practical possibilities of transmitting semen from a distance or the importance of what has actually been accomplished.

The succeeding chapters on sterility and reproductive efficiency deal with many matters of

No. 3014, Vol. 120]

practical importance besides pointing the way to further lines of work. It is interesting to note that some of these (for example, the question of the time of ovulation in the mare) have already been taken up. The sections dealing with parturition, genetic problems, grading, inbreeding, etc., are also full of interest, and the analysis of the show-yard records of the leading animals of different breeds contains much information which is not otherwise readily accessible. The chapter upon the development of farm animals includes many useful hints as to management and feeding. The last chapter, entitled "Fitting for Sale and Selling," is entirely practical, and directs attention to sundry matters of importance to every breeder who would market his products successfully

The book is well illustrated, many of the figures being photographs of outstanding specimens of farm animals. There are appendices on biometry and inheritance in horses, cattle, etc., besides a list of Pedigree Register Associations and a bibliography of references. In the second edition, which ought soon to be called for, these should be made more complete and the results of the latest researches incorporated.

F. H. A. Marshall.

### The Mathematics of Intelligence.

The Abilities of Man. their Nature and Measurement. By Prof. C. Spearman. Pp. viii+416+xxxiii. (London. Macmillan and Co, Ltd, 1927) 16s net.

ROF SPEARMAN'S new book, embracing his researches for some years past, is an exceedingly difficult book to review, and this for more than one reason In the first place it is distinctly written for the layman, and he is expected to take many things on faith to trust Prof. Spearman's mathematics and still more Prof Spearman's arithmetic. Now we can scarcely call upon the author of a popular book of this nature to justify either arithmetically or mathematically all his statements, but we do think that without overcrowding his pages he might have given us more of the numerical data on which his conclusions are based, so that we could test their adequacy without an immense amount of labour. This point is all the more to be emphasised because Prof. Spearman claims to have made by his investigations a "Copernican revolution in point of view." He tells us that he has "not - as all others - set out from an illdefined mental entity the 'intelligence' and then sought to obtain a quantitative value characterising this. Instead, we have started from a perfectly defined quantitative value g, and then have demonstrated what mental entity or entities this really characterises g (p. 411)

Now in order to test the justification for this statement that a Copernican revolution has been made in the study of the human mind, it is certainly needful to check not only the arithmetic but also the mathematics on which the claim is based, and neither of these are light matters, especially in such a brief review as this must necessarily be. But without some reference to the mathematics of the subject the real basis if our author's Copernican revolution cannot be rendered clear, nor without some arithmetic can we determine whether the values he gives are to be accepted straight off.

With much of the author's criticism of the definitions of intelligence hitherto proposed, we must undoubtedly agree: it is ably and amusingly written But Prof Spearman escapes any like criticism of himself by giving no definition of intelligence at all. He hypothecates that the measurement of a mental ability  $(A_n)$  is a function of two factors, a general factor g and a specific factor  $s_n$ , the former being a factor of all a person's mental abilities and the latter varying from ability to ability g is independent of the  $s_n$ 's, and the latter are independent of each other. Mathematically

$$A_n = \phi (g, s_n)$$

where  $\phi$  is a function as yet undetermined Prof. Spearman then proceeds to replace this general functional relation by a purely linear one, he in fact writes

$$A_n = c_0 + c_1 g + c_2 s_n$$

and all his conditions and his treatment depend on this linearity. Now the mind is a complicated organism, and quite as complicated as many physical phenomena, which do not obey any such linear relationship. What real justification is there for the adoption of such a form?

"The answer to this question is that our proof has depended upon usage of Taylor's theorem, according to which all mathematical functions, however complex, can, in general, be expressed in the above simple additive form with some approximation. This theorem has supplied the main foundation for the whole theory of correlation, from the original work of Bravais onwards; indeed, it is among the main props even of physics" (p. xv, Appendix).

We do not know how many physicists would agree with such a statement, but we presume that if they have adopted a linear relation, it is because it has been demonstrated experimentally to hold within some limited range. In the same way the only justification for linearity of regression is not Taylor's theorem, but observation and experiment. With our knowledge of the innumerable cases in which regression is non-linear, it is neither possible to assert that linearity is the main foundation of the whole theory of correlation, nor to accept it without foundation on experiment as a justification. Some light might have been thrown on the matter had Prof Spearman provided a distribution of g's for a population of reasonable size.

Accepting for the time this linear relationship, what flows from it? Without doubt, if a, b, c, d are four measurable abilities, the vanishing of what Prof. Spearman terms their tetrad differences, i.e.:  $r_{ac}r_{bd}-r_{ad}r_{bc}=0.$ 

Of course, in actual statistics this vanishing will depend upon the error of random sampling of a tetrad, and ultimately this error depends on the number (p) of individuals on which the correlations have been based. When p is small and the correlation r is large, the distribution of r does not follow the normal curve of errors, it is very far indeed from doing so. Correlations as high as 0.60 based upon 37 individuals deviate widely from the normal law, and many such occur in the chapter entitled "Proof that G and S exist." But whether the distribution of correlations be normal or not, it is perfectly certain on the basis of Prof. Spearman's own data that the distribution of tetrads is not normal. What it really is, even if the original mental ability correlations followed a normal law, no one at present knows. We are simply ignorant, and it is impossible to consider that any confirmation of the theory of two factors can be reached by placing a normal curve on top of the distribution of tetrads and judging merely by the eye of the goodness of fit. For example, the most ample data discussed by Prof. Spearman are those of Holzinger, involving 378 tetrads, and those of Simpson involving 3003 tetrads. If we apply to these distributions the normal curves for the theoretical standard deviations of these systems of tetrads, i.e. the actual values, not those computed by the approximate formulæ of Holzinger and Spearman from the mean correlation, we find for the first distribution, only one random sample in ten would be as bad a fit to the normal curve, and again for the second, that not one random sample in a million would give as bad a fit. Now we do not complain of these distributions failing to be normal curves, because we hold that

they ought not to be But we do complain of Prof. Spearman assuming them to be normal distributions, and using this as an argument in favour of his two-factor hypothesis. Indeed, afterplacing a normal curve on his data in the last case, Prof. Spearman writes (p. 146)

"This time, the two distributions, curve and rectangles, far from being totally discrepant as before, display instead one of the most striking agreements between theory and observation ever recorded in psychology Indeed, it would not be easily matched in any other science."

These words seem unfortunate not only because of the high improbability of the curve fitting the data, but also because there exists no theoretical reason why it should do so

Prof. Spearman starts with rendering his distribution of tetrads symmetrical, i.e making each tetrad once positive and once negative Hence he naturally has something that looks like the familiar cocked hat shape of the curve of errors Further. he can in this manner reach no test whatever of whether they are zero within the limit of random sampling. He has made his mean tetrad difference value zero artificially For Simpson's data the diagram has attached to it a scale lettering, in which 0.020, 0.030, 0.035 are printed where we ought to have 0.20, 0.30, and 0.35, that is, the tetrad differences are accidentally, but very unfortunately, given one-tenth of their true values, and accordingly appear very small. Underneath the diagram we read: Probable error == 0 061, Observed median = 0.062This latter is the only real test provided of the agreement of theory and observation It is not quite clear how Prof Spearman has obtained these figures The actual theoretical mean value of the 3003 squared tetrads is 0.007,887 corresponding to a theoretical standard deviation of 0 088,809, or if we use the term probable error, although the distribution is not normal, we have the value 0 059,901 instead of Prof. Spearman's 0.061. If we understand by Observed median, the observed quartile of the symmetrical tetrad difference distribution, it is 0.0581, not 0.062 as given on p 146. The question would then be whether 0 060 and 0 058 are in good agreement But a better way to approach the problem is probably to note that the theoretical mean squared tetrad is 0 007,887, while the observed value is 0 009,817 The difference between observed and theoretical mean is thus 0 001,930 If we could measure the probable error of the mean in the usual way on 3003 observations with a standard deviation of 0.017,769, it would be 0.000,219, or the deviation would be some 8.8 times the probable error. We should accordingly conclude on these data that the new Copernican theory, so far from being in "striking agreement" with observation, signally failed.

While, however, we know the theoretical mean squared tetrad value—always, alas' on the basis of variates following a normal distribution—we do not know the true probable error of this squared tetrad value. The reason for this is that the tetrads are not like the individuals of an ordinary frequency distribution merely correlated by the fact that the size of the sample is fixed. On the contrary, there is correlation produced by the fact that in this case the 3003 tetrads are functions of only 91 individual correlations, and this correlation is very high in the case of the triplet of tetrads based upon sets of four correlations. To determine the true probable error of the sum of the squared tetrads will be a problem which will task the ablest mathematician, even if he assumes (i) that the original mental variates follow the normal law and (ii) that the correlation coefficients follow-which we know they do notthe same law. At present no one can say whether or not the sum of the squared tetrads differs from its theoretical value by amounts which can be accounted for on the basis of random sampling. But we can say that what Prof Spearman considers proofs of his theory are not proofs, and that much mathematical work remains to be done before we shall even be in sight of a proof With the failure of Chapter x., that is, "Proof that G and S exist," the very backbone disappears from the body of Prof. Spearman's work. Even if the correlations of mental abilities were taken to vary at random with a given standard deviation round a given mean, the distribution of the resulting tetrads would form an approximately normal system, and many tetrads would vanish or nearly vanish; it would be idle to pick these out as special illustrations of But this is m fact what occurs in the later chapters of "The Abilities of Man"

We have confined our criticisms to one point: there are others, especially in the mathematical appendix, where we hold Prof Spearman's analysis to be defective. But it seems to us that there is one main question. Is the experimental proof of the existence of a general and of specific factors on which the author bases his discussions in this work valid? Prof. Spearman holds that it is, we hold that it is not. The truth can only be ascertained by lengthy arithmetical and mathematical investigations, unsuited to a review of the present kind.

One advantage of the publication of this book

will be that the attention of mathematicians will be directed to the real difficulties of the analysis, and this should lead, in conjunction with the psychologists, to a fitting series of tests in which probably some fifteen to twenty abilities should be measured on four or five hundred individuals. In particular, the abilities must be selected beforehand, and none rejected after analysis because they do not satisfy the condition of zero tetrad difference. Prof. Spearman has had the merit of directing attention to the subject, but his book will do more harm than good if it leads the non-mathematical psychologist to believe that the author has proved his hypothesis. It may possibly turn out to be true, but the proof will have to be far more rigid than anything so far provided in "The Abilities of Man."

### The Exploitation of Tropical Africa.

An African Eldorado: the Belgian Congo By T Alexander Barns. With an Introduction by Sir Louis Franck. Pp xv+229+23 plates+4 maps (London: Methuen and Co, Ltd., 1926) 15s net

Out in the Blue. By Vivienne de Watteville With a Preface by the Hon. William Ormsby-Gore. Pp. xvi+254+65 plates. (London · Methuen and Co, Ltd., 1927.) 18s. net.

HESE two volumes deal with two different aspects of the exploitation of central Africa. Mr. Barns is chiefly concerned with the development of the mineral and agricultural resources of the Congo basin, particularly those parts under Belgian control. Miss de Watteville sees tropical Africa through the eyes of a naturalist. Mr. Barns paints an illuminating picture of the fertility of tropical soil, the scope for the development of the wealth of its natural vegetation, its metalliferous ores and precious stones, and indicates the respective rôles of the white man and the native in this development. Miss de Watteville's only concern is the exploitation of the fauna of the tropics in the interest of the Berne museum, by the authorities of which she and her father, the late Bernard de Watteville, were commissioned. Within the compass of 225 pages Mr. Barns deals with most of those aspects of African life and travel which interest most of us, whatever our peculiar interest may be, whether geology, botany, zoology, history, or anthropology. Miss de Watteville devotes the same amount of space to a straight tale of systematic killing of wild animals and the preparation and preservation of their hides for a museum.

Lingering yet in our memory is the account given by the late E. D. Morel of the horrors of the Leopold regime in the Congo, an account which aroused the peoples of Europe to effective protest Now, according to Mr. Barns, Belgian administration in the Congo is characterised by as much regard for the welfare and progress of the natives as the British administration in West Africa Louis Franck, former Belgian Colonial Minister, who contributes a preface, describes the official attitude thus: "We believe in the progress and future of the black man, and we want to pave the way for him towards a better standard of life, a great improvement in health and efficiency, and a . We are absolutely opposed higher civilisation. to anything like colour bar or race discrimination in the opportunities offered to black labour"

The difficulties of the Belgian administrators are common to all aliens in tropical Africa faced with great difficulties of communication which the mighty waterways do not altogether surmount, with multitudinous insect pests—a constant menace to man and beast—the conservatism of the natives, the diversity of tribes and languages, pygmies in close proximity to giants, and the shortage of capital. On the other hand, they have certain special advantages. "All its eggs are in one basket." The upturned edges of the basin of the Congo are a storehouse of mineral wealth in amazing abundance, while in the well-watered plains the oil-palm, rubber, rice, cotton, sisal, and other economic plants flourish, and there is rich pasturage for cattle on the slopes of the basm In the south there are mountains of copper in the Katanga Copper Belt, with gold, tin, radium, and cobalt in close juxtaposition. In the Mandated Territory of Ruanda, on the east of the Rift Divide, is one of the most populous and richest cattle countries in Africa, the cattle possessing the advantage of immunity from East Coast fever. In the north-east are the Kilo and Moto gold mines, and again to the south, in the Kasai, extensive diamond fields are being worked. On the material side, therefore, Mr. Barns regards the Belgian Congo as "an Eldorado," a country which promises a rich return for men of small means as well as for development companies with large financial resources.

The main interest of this arresting volume lies, however, not so much in the author's description of the material resources of the country, as in his description of the scenery, of the peoples, their habits and customs, their arts and crafts, of the flora and fauna, and his incidental notes, some of which are of particular interest to scientific

workers. For example, in the high country in the Kıvu craterland, there are no tsetse-fly, but the cattle suffer from tsetse-fly disease In the flydistricts around Lake Edward and along the Semliki river, man and his domesticated live-stock have managed to hold their own against the epidemics of nagana and sleeping-sickness that have so often ravaged the district. The African elephant, he tells us, "is very free from disease. can thrive at all elevations from the sea to 13,000 feet (the equatorial snow-line), can stand alike either cold or heat and can obtain nourishment from a greater variety of vegetation than any other animal" Mr Barns's book, with its beautiful photographs, will add to his already considerable reputation as a charming and accurate observer of the Africa he loves.

To those who are interested in the details of a 'collecting' expedition, and wish at the same time to read an amazing story of a girl's pluck and persistence after the tragic death of her father in an encounter with a lion, Miss de Watteville's book can be recommended.

A. G. Church.

#### Our Bookshelf.

The Chemistry of the Natural and Synthetic Resins.

By T. Hedley Barry, Alan A Drummond, and
Dr. R. S Morrell. (Oil and Colour Chemistry
Monographs) Pp. viii + 196. (London: Ernest
Benn, Ltd., 1926.) 21s. net.

This volume is divided into two sections, dealing respectively with the natural and the synthetic resms. Perusal of the former of these sections gives the impression, only too correct, that our knowledge of the chemistry of the natural resins consists mainly of information concerning botanical sources, methods of collection, and of a few variable 'constants.' Practically only in the case of colophony, the commonest resin, has any approach been made towards elucidation of the chemical constitution of complex bodies present in these natural products; it is not surprising, therefore, that the author has allotted to this particular topic one-third of the space in this section.

Following a brief account of the botanical origin and nature of resins by Dr. Willis, the first two chapters deal with general physical and chemical properties. Only resins of interest to the varnish maker are considered, and these are classified under the following headings hard and semi-hard resins, spirit-varnish resins, colophony, soft resins, true lacquer, and shellac.

Despite systematic attempts at the conservation of sources of supply, the partial exhaustion of the natural resin constitutes a danger which should not be overlooked; the introduction of the synthetic resins, therefore, is most timely. Although our knowledge of the chemical processes involved has lagged behind the technical side of the subject, investigations during the last few years have afforded considerable insight into the various causes and stages of resimification; these are well set out in the volume under notice. The synthetic resins, other than those obtained by treatment of the natural varieties (e.g. by esterification of colophony and copal) which are also dealt with in this section, fall broadly into two classes, the condensation resins and the polymerisation resins. These are considered under their respective headings, other products, such as the treated phenol-formaldehyde resins and those from urea and thiourea, are considered separately. The section concludes with a brief chapter on the methods of testing synthetic resins

The book covers a very large field, and certainly presents in modest bulk a useful summary of our present knowledge of the products discussed. The index is adequate, although one or two omissions have been noted. Unfortunately there is an unduly large proportion of misprints, mainly in the first section; names mis-spelled in the text persist in the index, whilst some references are incorrect

B. A. E.

Spectroscopy. By Prof E C. C Baly. (Text-books of Physical Chemistry) Third edition In 4 volumes Vol. 2 Pp vin + 398 + 3 plates (London: Longmans, Green and Co, Ltd, 1927) 18s net

PROF. BALY'S well-known work on "Spectroscopy," which formed a single volume in the first edition of 1905, as well as in the second edition of 1912 and 1918, has now begun to grow so rapidly that the third edition is to appear in four volumes instead of the two volumes that were originally contemplated. This expansion is an almost inevitable sequel to the amazing growth of the subject since Bohr first introduced the quantum theory into spectroscopy in 1913; and no one will grudge the author more space in which to expound the wider knowledge that has been gamed during the subsequent years. These topics, however, are not included in the present volume, which contains only one indexed reference to Bohr, and none to the quantum theory

The subjects dealt with are: (i) interference methods, (ii) methods of illumination, (iii) the nature of spectra, (iv) fluorescence and phosphorescence, (v) the photography of the spectrum. Thus a detailed account is given of the use of an interferometer in the study of double stars, with diagrams of the apparatus used at Mount Wilson, which look rather like a 'Meccano' model, until it is seen that the beams are made from 10-inch and 12-inch steel channel The methods of illumination range from flame spectra to the 'explosion' of wires by means of a condenser discharge. The chapter on the nature of spectra deals mainly with the structure, width, and sharpness of the lines, e.g. the resolution of the green mercury line into a dozen components and the classification of these components into three triplets and three remaining unrelated lines. The chapter on fluorescence and phosphorescence covers a wide field, including Wood's work on resonance spectra and on fluorescence, the work of the two Becquerels and of Nichols and Howe on the fluorescence of uranyl salts, Stewart's experiments on Tesla luminescence spectra, and a large amount of work on phosphorescence and luminescence of various types. The final chapter on photography includes a considerable amount of information supplied by Dr. Kenneth Mees, and also a section on sensitisation written by him.

The author is to be congratulated on completing his second volume, and preparing the way for the description in Vol. 3 of those modern developments which have given to spectroscopy a predominant position in atomic physics, comparable to that which it held when Bunsen first applied the spectroscope to the study of the chemical elements.

Über die Natur und Bildungsweise der mannen Eisensilikate, insbesondere der chamositischen Substanzen · ein Beitrag zur chemischen und mechanischen Sedimentation. Von Dr. Karl C Berz. (Fortschritte der Geologie und Palaontologie, Heft 11.) Pp viii +365-522+6 Tafeln (Berlin: Gebrüder Borntraeger, 1926) 12 gold marks.

During recent years considerable progress has been made in the description of ferriferous sediments. Works by Hayes on the Wabana iron ore (1915), by Cayeux on the French secondary ores (1922), and by Slavik on the Czechoslovakian deposits have contributed substantially to the elucidation of the chamosite-bearing rocks, while corresponding researches have been carried out on the English iron ores by the Geological Survey of Great Britain since 1920 (see "Summary of Progress for 1922" (1923), and Special Reports, vol. 29 (1925)). The present work contains a review of this question on similar lines to the above, dealing in some detail with the German deposits. The author limits himself to the discussion of existing literature on the subject, with a few additional descriptions, and provides a useful account of many rather inaccessible papers on local ores. In dealing with general literature the author has evidently been somewhat at a disadvantage, for of the works above mentioned not one appears in the bibliography, though there is passing reference in the text to the report by Hayes.

The views advanced are substantially in agreement with those generally current, the ores being regarded as primary sediments. Interesting sketches are given of the tubular organisms sometimes found in the ooliths; the author does not regard them as having played an essential part in the formation of the oolith, but rather as parasitic growths accidentally preserved in the inorganic structure. Chamosite is described in detail from the mineralogical viewpoint, but the corresponding account of glauconite is scarcely adequate, and more space might perhaps have been given to the discussion of the glauconitic sediments. As is perhaps inevitable in a work of compilation, the tone of the discussion appears somewhat speculative,

for the origin of these rocks has been the subject of a great variety of conflicting theories, but many useful observations are recorded. The microstructures are illustrated by twelve photographs of chamositic sandstones and colitic ores from French, Belgian, and German localities.

A Survey of American Chemistry. Vol. I.: July 1, 1925, to July 1, 1926, including Reports from Scientific Committees, Division of Chemistry and Chemical Technology, National Research Council Edited by William J. Hale, in co-operation with Clarence J. West (Published for National Research Council.) Pp. 257. (New York: The Chemical Catalog Co., Inc, 1927.) 2 dollars

This compilation will afford actual assistance to chemists in so far—only so far—as its prearranged national limitations have been ignored by the authors of its thirty-four chapters. Summaries of the literature of chemistry are increasingly acceptable to the chemist, whether investigator, teacher, or student, provided that it may reasonably be supposed that relative scientific value is the only criterion of the consideration or rejection of subject matter. Moreover, the student of American history would obviously be better served if he could be provided with some means of ascertaining whether the numerous reports of investigations which are here admirably chronicled and discussed were as American in origin as the name of the journal in which they appeared would indicate; if, too, he could gauge the extent of the lacuna represented by the publications of Americans in European journals. It will be obvious, also, that the granting of a patent is no guarantee that the work is indigenous.

In any case, both chemists and historians will regret the absence of an index; not even a list of authors is provided. In some chapters, however—the net is spread very wide over pure and applied chemistry—it is evident that an attempt has been made to present a summary not only of considerable interest but also of permanent value. A. A. E.

Gmelins Handbuch der anorganischen Chemie.
Achte völlig neu bearbeitete Auflage. Herausgegeben von der Deutschen Chemischen Gesellschaft. Bearbeitet von R. J. Meyer. System-Nummer 19: Wismut und radioaktive Isotope. Pp. xxii + 229. 33 gold marks. System-Nummer 20: Lithium. Pp. xxiv + 254. 37.50 gold marks. (Berlin: Verlag Chemie G.m.b.H., 1927.)

THE parts of Gmelin's new "Handbuch" which deal with lithium and bismuth, like the earlier parts, show abundant evidence that a painstaking and exhaustive review of the literature up to July 1926 has been made. Following the general plan of the work, the parts open with notes on the history and distribution of the elements. Then follows a comprehensive survey of their physical, electrochemical, and chemical properties, and a similar scheme is adopted in dealing with compounds of these elements with such other elements as precede

them in the scheme (see Nature, Mar 5, p. 346). That the search through the literature has been thorough may be inferred from the fact that the description of one salt alone (lithium chloride) occupies fifty pages and contains detailed numerical data relating to hydrates, to solutions in water and in organic solvents and to complex amminechlorides. A summary of recent work on the atomic dimensions, atomic structure, and isotopes of lithium is given, whilst the radioactive isotopes of bismuth are fully described in a special section, which includes not only detailed references to recent papers but also a synopsis of the general literature on the subject.

Ancient Egyptian Materials. By A. Lucas. Pp. viii + 242. (London: Edward Arnold and Co, 1926.) 7s 6d. net.

In his preface Mr Lucas points out that it is only in recent years that the archæologist has availed himself of the assistance of the chemist. With certain reservations this is correct, and it is true that a great deal of detailed work has still to be done. A reference to the sections in the present book which deal with the use of metals will show to what an extent questions relating to the source and early history of copper and bronze must remain in suspense until analyses of specimens of these materials from early sites and early workings have been made. Whence came the tin which was imported into Egypt? Mr. Lucas thinks that it may have been Spain, and inclines to the view which relegates Cornwall as a source of copper to the Middle Ages. If the edict of Sargon is correctly interpreted as referring to a "land of tin," this would give a mention of that metal earlier than that in Homer quoted by the author; but Spain seems a far cry from Mesopotamia at so remote a date as 2750 B c.

This is one only of a number of problems which is raised by Mr. Lucas's book. Each of the materials used by the ancient Egyptians is taken in turn and described, its nature or composition examined, and its use, and wherever possible its place of origin and the date of its first employment given. Appendices deal with chronology and, what will prove especially helpful, give a number of analyses of metals and other materials. One point brought out very clearly by this method of treatment is the indebtedness of Egypt to western Asia.

The Aborigines of the Highlands of Central India. By B C Mazumdar. Pp. vi+84. (Calcutta: The University of Calcutta, 1927.) n p

This is a small but valuable contribution to our knowledge of some hill tribes in central India. The author, who is lecturer in cultural anthropology at the University of Calcutta, has first-hand experience of the Sabara Kols and other neighbouring tribes. The pamphlet contains a description of the customs and organisation of these natives, as well as an attempt at tracing the historical relationships of these aboriginals to the other inhabitants of mid-India.

### Ionisation in the Upper Atmosphere.

THE more important agencies which may conceivably cause the ionisation of the upper atmosphere of the earth are the ultra-violet light,  $\alpha$ - and  $\beta$ particles, all of solar origin, the penetrating radiation of cosmic origin, and the ionising radiations from terrestrial sources. The last mentioned may perhaps be ruled out immediately because of the fact that the conductivity of the lower atmospheric strata increases rapidly with the height for the first few kilometres. The possible effects of these ionising agencies have been considered in papers by Chapman and Milne, Benndoif, Elias, Lassen, and others. Recently, experi-ments with the electromagnetic waves of wireless telegraphy, together with theories of the propagation of these waves over the surface of the earth, have led to more definite information about the ionisation in the upper atmosphere, and it has been of interest to examine again the causes of the ionisation.

The experiments of Breit and Tuve with 70 metre waves, of Heising with 57 and 111 metre waves, of Wagner and Quack with 15 and 16 metre waves, and the experiments of Taylor on the skip distances of waves below 50 metres and the theoretical considerations of Taylor and Hulburt of these skip distances, show that the electron density N increases with the height Z above the earth, reaching a value of about  $4\times 10^5$ ; above the height where N has this value, nothing is known of the electron density except that it does not go on increasing. Although the wireless data are none too extensive, it may be taken that in summer (for the north temperate zone) the height where N is of the order 105 is roughly 150 km. at midday, rising to 300 km. at 2 A.M., and in winter is around 200 km. at midday and 600 km. at night. To this may be added an interpretation from the experiments of Appleton with 400 metre waves that N is of the order of 103 at about 100 km. for a June night in England.

Because of the diurnal variation in the ionisation, we chose the ultra-violet light of the sun as being the ionising agency deserving first consideration. In order to make an explicit calculation of the ionisation of the temperature, the pressure, and the constituent gases and their partial pressures, must be known at each height in the upper atmosphere. These we may take as given completely in the classical thermodynamic isothermal equilibrium theory of Humphreys, Jeans, and others. There is a question as to the existence of hydrogen in the upper atmosphere, but the conclusions given later are much the same whether hydrogen is there or not. There is also the question of ozone, or oxygen, which may be of great importance.

Further, the law of the recombination of the electrons with the positive ions must be known. When the electron collides with a positive ion, in order for recombination to occur, energy must be dissipated in some way, either (a) by a third body, such as another molecule—this is J. J. Thomson's theory of recombination, and complete formulæ are available—or (b) by radiation (simple formulæ for this case are easily derived). We must also recognise the possibility of the electron attaching itself to a neutral molecule, for when it does this, thereby producing a negative ion, it is no longer as energetic a refractor of the wire-

less rays. The oxygen molecule is the only important one in this connexion, and the values of the attachment coefficient measured in the laboratory for pressures of 10 mm. of mercury and above must be extrapolated to pressures below  $10^{-2}$  mm., perhaps a questionable extrapolation. Using all these things with (a) and making entirely acceptable assumptions as to the amount of ultra-violet light from the sun m the spectral region useful for ionisation, the N, Z curve rises rapidly from N=0 at Z=100 km. to  $N=4\times 10^5$  at Z=150 km; above this height N falls off slowly. With (b) the N, Z curve is much the same as with (a), but N falls off more rapidly with Z above 200 km. Either of these N, Z curves is main accord with the wireless data for full daylight conditions. One might be content with the agreement, for the present, were it not for what happens at night. At night, after the removal of the sun's ultra-violet radiations, the calculated N, Z curve sinks down somewhat towards the Z axis, but with no great change in the height at which N rises to  $4 \times 10^5$ . This is distinctly contrary to the indications of the nighttime wireless data, which require the electron bank to move up, so that the height at which  $N=4\times 10^5$  at midnight may be roughly twice the midday height.

In an endeavour to bring the calculations into accord with the wireless experiments, we may abandon the classical pressures, increasing them by a factor of  $10^2$  or  $10^3$  for heights above, say, 150 km, and at the same time increasing the partial pressure of the oxygen at these heights. In this way we can obtain the electronic densities at night and day required by the data of the shorter wireless waves. In increasing the classical pressures we are doing exactly what Lindemann was led to do in his theories of the meteors. He has suggested that the formation of ozone, with its attendant strong absorption from 2000 Å.U. to 3000 Å.U., may be a sufficient cause of temperatures and pressures higher than the classical ones. The existence of oxygen in the higher levels is supported to some extent by the recent identification of the auroral line with oxygen. There remains, however, a difficulty with the 400 metre waves of Appleton. A simple smooth increase of the total gas pressure and the partial oxygen pressure, which yields an ionisation satisfactory for the shorter waves, wipes out the night-time ionisation below Z = 130 km.

A way out is to assume an irregularity in the pressure-height curve; for example, to assume that the pressure drops off with the height, then increases to a maximum at 80 km. or 100 km., and decreases thereafter. Or, one may assume an ozone layer at this height and that the ozone does something peculiar to the ionisation, such as disintegrating slowly to oxygen during the night, thereby in some way maintaining the ionisation. Chapman has pointed out this possibility. Further, one may put aside hypotheses of the kind just mentioned and assume that the pressures of the constituent gases of the upper atmosphere are those of the classical calculation and that other agencies of ionisation exist besides the ultra-violet light, which are effective by night as well as by day. It seems that such a view meets with no immediate objections. For example, the number of a-particles from the sun necessary to produce the desired ionisation, if they are similar to those of radium-C, requires a small and quite permissible amount of radium at the solar surface. One can speak less definitely of  $\beta$ -particles of solar origin and of cosmic radiation. In a final summing up one may have to reckon with all of these possibilities.

E. O. HULBURT.

Naval Research Laboratory, Washington, D.C., June 16.

## The Total Reflection of X-rays.

As has been discovered by Compton, 1 X-rays falling on a polished surface at small glancing angles are totally—or at least nearly totally—reflected This phenomenon was explained by Compton as being due to the fact that the index of refraction of X-rays is a little less than unity:  $n=1-\delta$ , where  $\delta$  is small compared 2 with unity

Indeed, applying Fresnel's well-known expression for the intensity of reflection, we find in this case for

small glancing angles  $\phi$  the formula

$$\frac{I_{\tau}}{I_0} = \left| \frac{\sqrt{\phi^2 - 2\delta} - \phi}{\sqrt{\phi^2 - 2\delta} + \phi} \right|^2 \quad . \tag{1}$$

for the fraction of the incident energy which is reflected. A graph of this function (for  $2\delta = 6 \times 10^{-5}$ ) is given in Fig. I (curve A); it shows that below a certain critical angle  $\phi_0$ , given by  $\phi_0 = \sqrt{2\delta}$ , the reflection is total, whereas for angles  $> \phi_0$  the reflect-

ing power falls down rapidly

Since its discovery the phenomenon has been studied by several authors, but so far as I know it has not occurred to any one of them that this theory needs some extension in so far as the absorption has also a considerable influence on the reflection. According to elementary wave-theory we may take this into account 3 by putting in Fresnel's formula the complex value  $n = 1 - \delta + \epsilon i$  for the index of refraction, where 2ε is the absorption coefficient (for the energy) taken for  $1/2\pi$  times one wave-length. Instead of (1) we then get ·

$$\frac{I_{\tau}}{I_0} = \left| \frac{\sqrt{\varphi^2 - 2\delta + 2\epsilon \imath} - \phi}{\sqrt{\varphi^2 - 2\delta + 2\epsilon \imath} + \phi} \right|^2. \qquad (2)$$

This function is given in the curves B and C of

The values taken for the constants,  $2\delta = 6 \times 10^{-5}$ ,  $2\epsilon = 0.2 \div 10^{-5}$ , and  $1.5 \times 10^{-5}$  correspond to the reflection by iron of wave-lengths a little greater and a little smaller than 1740 X.U., this being the wave-length of the K-absorption discontinuity of iron.

I have performed some experiments showing the dependence of the reflection upon the absorption in a marked manner. The device used was a very simple one. Two identical rectangular mirrors of stamless steel were put together, their optically polished surfaces confronting each other. These surfaces were kept parallel and at a distance of 50µ apart from each other by putting small pieces of aluminium leaf between them at the four corners.

The 'slit' so formed was then put horizontally between the focal spot of an X-ray tube and the vertical slit of an X-ray spectrograph—the method being not unlike the 'method of crossed prisms

in optics.

Fig. 2 is a reproduction of a photograph obtained in this way (tungsten target; exposure 20 hours); it contains the spectral region on both sides of the K-absorption discontinuity of iron ( $\lambda = 1740 \text{ X U.}$ ).

If there were no such phenomenon as reflection against the steel plates, we should have obtained a spectrum of exceedingly short lines the height of which would be determined by the distance between the steel plates. Owing to the reflection against these plates the lines are much higher, their intensity

 W. Linnik and W. Laschkarew, Zeuschr f Phys. 38, 659; 1926.
 My attention was first directed to this point by Prof. Kramers
 The mirrors were supplied by Messrs Ottwav and Co., Ealing.

in vertical direction giving a measure of the reflecting power of the steel at the corresponding angle. complication is introduced by the fact that the radiation corresponding to relatively great angles is repeatedly reflected at the plates before leaving the recorded on the plate by the horizontal strice (these strice being due to megularities at the edge of the

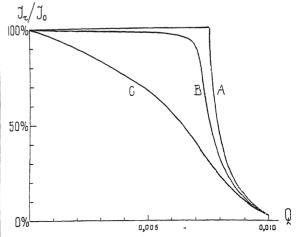

Fig. 1.—Theoretical curves for the reflecting power of non-tor X-rays as a function of the glancing angle  $\phi$  (in the figure Q stands for  $\phi$ ). A, when the absorption is neglected, B, with weak absorption (long wave-length side of K-absorption discontinuity), C, with strong absorption (short wave-length side)

plates). If we wish to compare the distribution of intensity in vertical direction with the theoretical curves B and C, this influence may be taken into account When this is done, the agreement between theory and experiment is sufficient, the limit of visible blackening corresponding to a little less than the angle for which, according to theory, the intensity should be reduced to half its mittal value.

So far we have considered only the influence of the wave-length on the reflection caused by a change of  $\epsilon$ (tormula (2)) The quantity o, however, also changes with the wave-length If we look apart from the neigh-

Fig. 2 —Photograph showing the reflecting power of non-tor  $\lambda$ -rays on both sides of the K-absorption discontinuity 1675 W LI, 1740 = Fe K-abs; 1753 = Fe  $K\beta_1$ .

bourhood of the absorption-edge, this should cause the 'critical angle' of reflection (in our experiment the height of the spectrum) to be proportional to the wave-length. This has been verified already by Compton, and is confirmed by my experiments (covermg spectral regions from 0 5 Å.U. to 2 Å U.), with considerable accuracy.

In the immediate neighbourhood 5 of the discontimusty, however, we should expect a decrease of

<sup>&</sup>lt;sup>5</sup> H. Kallmann and H. Mark, Ann. d. Phys., 82, 585; 1927.

the height of the spectrum, the late of this declease being particularly large quite near to the edge Whether such a phenomenon exists or not is a question which our experiments as yet are not able to settle; but it is hoped to get evidence on this point in the near future.<sup>6</sup>

In conclusion, I wish to thank Prof Coster and Prof. Kramers for the kind interest they have shown in this investigation.

#### A Sonic Interferometer for Liquids.

From thermodynamical considerations alone it should be possible to calculate the number of degrees of freedom, and consequently the association of molecules in the liquid state, if one could only determine the numerical difference between the specific heats at constant pressure and at constant volume. It is practically impossible, however, to obtain direct measurements of liquids at constant volume because of the elasticity of the walls of the containing vessel. But this difficulty can be obviated if the velocity of a compression wave in the liquid can be ascertained with sufficient precision, because the numerical difference between the specific heats can, by the aid of Newton's equation, be expressed as a function of the temperature, the coefficient of expansion, and the velocity of a compressional wave

With these thoughts in mind, and taking advantage of the work being conducted in this laboratory by R. W. Wood and A. L. Loomis on the physical and biological effects of high-frequency high-intensity-sound waves, we have constructed a sonic interferometer' capable of measuring the velocity of compressional waves in small quantities of liquids with an accuracy of one part in three thousand. This instrument is in many respects the sonic analogue of

the Perot-Fabry interferometer.

Corrections for the elasticity of the containing vessel can be entirely eliminated by using a sufficiently high frequency so that the wave-length is small in comparison with the diameter of the radiating source. We use, as a radiator, a piezo-electric crystal quartz disc 100 mm in diameter and 12 mm, thick carefully ground and polished plane parallel, which we cause to oscillate at frequencies from 200,000 to 400,000 cycles per second, producing waves from 3 to 8 mm. in length. The frequency of the oscillating circuit is determined with a precision wave meter. Contrary to the usual practice with piezo-electric crystals of allowing them to oscillate at their own natural frequencies, we have found that much more precise measurements can be obtained if the crystal is driven at certain frequencies well removed from the natural frequency of the crystal, for then the crystal resonance does not partially mask the exact moment when resonance is established in the liquid The small glass vessel containing the sample of liquid under investigation is placed on the oscillating crystal. When properly adjusted, the compressional waves pass upward through the plane parallel bottom of the vessel into the liquid and, because of the shortness of the waves compared with the dimensions of the vessel, pass upward in the liquid as strictly plane waves. They are then reflected from a plane surface immersed in the liquid and made parallel with the quartz disc. By carefully adjusting the distance of this surface

<sup>6</sup> From my photographs may be concluded that this effect is at any rate smaller than Kallmann and Mark's theory would lead us to expect.

with a fine micrometer screw standing waves can be produced. It is thus possible to measure 20 or more half wave-lengths with a precision of 1 100 mm. At each nodal point a small neon light loosely coupled to the circuit is extinguished, due to the reaction of the system of standing waves upon the crystal.

Characteristic results are presented in the accompanying table. These results are subject only to a revision of our wave meter calibration, and are of a self consistency one order higher than the number of places here presented. No variation in velocity with frequency can be detected within the frequency limits which we have employed, nor can any difference be detected when we vary the material and dimensions of the containing vessel.

VELOCITY OF SOUND WAVES IN LIQUIDS IN METRES/SEC

Material	Temperature			
	5°	15°	25°	35°
Distilled Water 1-0% NaCl sol 2-5% "" 5-0% "" Mercury Carbon Disulphide Chloroform	1439	1477 1487 1510 1540	1509 1520 1539 1569 1469	1534 1542 1561 1589 1468

The data published on the velocity of sound in liquids are for the most part in very poor agreement, and the methods employed, with the exception of direct determination in open water, involve serious corrections, the wave-lengths in general being large in comparison with the containing vessel. It is of interest to note that careful and laborious measurements have been made of the velocity of sound in the open sea by ascertaining the time of travel of a compressional wave for a distance of 53 nautical miles (E. A. Eckhardt, Phys Rev., 24, 452; 1924). The velocity thus obtained is 1492 metres/sec at 13° C. As a check we found at the same temperature a velocity of 1480 5 metres/sec for a 10 per cent. sodium chloride solution and 1503 metres/sec. for a 2 5 per cent. sodium chloride solution It is of interest to compare these results with that for distilled water from which substantially all the air has been removed, which at 13° C. we found to be 1470 metres/sec. The presence of small quantities of dissolved air materially affects the velocity

We are at present engaged upon a comprehensive study of water and of its solutions with several salts, and of a number of organic compounds and their mixtures, which we expect to publish shortly, together with a detailed description of the instrument.

#### The Flying Fox Pest in Australia.

The Council for Scientific and Industrial Research is finding difficulty in devising methods for coping with the large fruit-eating bats, commonly known as "flying foxes," which are a most serious menace to fruit growers in Queensland and New South Wales. There are five species in Australia, the commonest by far being *Pteropus poliocephalus*. Nocturnal in habit, and very gregarious, these animals live in large camps of hundreds of thousands of individuals. They migrate according to season and food supply, but

usually return to the same camps in successive seasons. In the daytime they cling to the branches of trees in dense numbers; they are restless and alert and a single gun-shot will put a whole camp to flight At night they depart in search of food such as fruit, berries, eucalyptus flowers, and honey. They are particularly fond of cultivated fruit, and the damage that they can do m an orchard in one night is appalling. The amount of fruit actually eaten is relatively small; the ground is strewn with fallen material which has been merely nibbled or claw-marked.

Many obvious methods of destruction have been Shooting is expensive Strychnine poisoning in the orchard is successful to an extent. Poison gases in the camps are not effective because of the timidity of the bat: it is almost impossible to give a lethal dose before they take wing. Infection with Bacillus typhi marium is said to have cleared Samoa of the pest some years ago, but we have failed to verify the report and it is understood that Samoa is still badly infested. A small 'flammenweifer' has been tried but, besides being dangerous and expensive, it is not suitable for general use

All these, and other, methods have been more or less successful in killing the creatures, but in every case the scale of possible operations is hopelessly inadequate. Wholesale slaughter must be achieved if the pest is to be minimised or even merely kept from increasing. Perhaps the most effective attack will be by biological means. Can any biologist suggest a sound line of investigation which the Council for Scientific and Industrial Research might follow?
A. C. D RIVETT.

Commonwealth Council for Scientific and Industrial Research, 314 Albert Street, East Melbourne.

#### Meteorology: Ancient and Modern.

I Do not disagree with those who hold that a review is not an appropriate subject of correspondence for the reviewed; but a paragraph by Mr. W. H. Dines in the issue of Nature for June 25, puts so compactly, as it were in a nutshell, a question of importance to a wider circle than that which is interested in the study of weather, that I may venture to ask for a little space in which to crack the nut and get at the kernel.

Mr. Dines writes (p. 917):

"The author prefers to measure radiative energy in a dynamical unit and states that he finds kilowatts per square dekametre the most convenient. The more usual unit is a gram calorie per square centimetre per minute, but something may be said in favour of gram calories per day, since a gram calorie is more generally understood than a joule and the day is the natural meteorological unit."

This raises the very important question of systematic units for the geophysical sciences. One of my reasons for preferring the kilowatt per square dekametre to the gram calorie per day is precisely that very few people understand what a gram calorie means, and the day that Mr. Dines refers to is not, in fact, a natural unit of time.

Like the questionist who could not define a parallelogram, though he would know one if he saw it, I could not myself say, off-hand, what exactly a gram calorie is for the purposes of computation. I venture to think it doubtful if Mr. Dines could, and would be prepared to risk a little upon the chance of not finding a single member present at a meeting of the Royal Meteorological Society, or (if I might whisper it) of the Royal Society itself, who could give, without reference to a book, an arithmetically workable reply to the question: What is a gram calorie? If any one

were fortunately so encyclopædic, the probable answer would be 41.8 million ergs.

I have also a deeper reason than that. The grand achievement of the first half of the nineteenth century was the discovery that heat had a dynamical equivalent and that energy is always conserved. From that principle we have learned that the energy of a hailstone in the clouds, of a lightning flash, and of a beam of sunshine, are all convertible one into another, perhaps through heat If, therefore, we really mean what we say in enunciating the principle of conservation of energy, it is urgently desirable that we should keep their identity always in view by expressing all in simple multiples of a single unit.

Now estimating the energy of a lightning flash in gram calories simply 'is not done' We naturally run to ergs for lightning, and if the lightning will not go to heat for its unit, heat might go to the lightning; and the more reasonably, since the heat unit only becomes a commensurable member of the family when

it also is expressed in ergs.

There is no such ambiguity or uncertainty about the kilowatt or the joule I go so far with Mr. Dines as to say that I am sorry that the names Watt and Joule, or any other name that does not explain itself, should have been attached to 107 ergs. I am sometimes exasperated by having to get down a book of reference to confirm or contradict my memory. A kilowatt-hour is an ugly unit, but it is what I, and many others, have to pay 7d. for, so I suppose even if I do not understand it and Mr. Dines does not, the Board of Trade as well as other consumers must think they do.

The word 'hour' leads me to the other lobe of the kernel, the day as a natural unit for meteorology. What, after all, is a day? In another part of his review Mr. Dines rallies me about a chapter on the Kalendar not being, strictly speaking, meteorology. Yet I am quite sure that without that chapter Mr. Dines and I would not understand each other as to what is meant by a day, and with that chapter to refer to I believe I should be able to convince Mr. Dines that by 'a day' he does not really mean a day but an arbitrary unit of clock time, 86,400 seconds, which is only a real day four times in a year.

These things are perhaps of little importance in the physics that is sheltered by a laboratory roof, and indeed the idiosyncrasics of things like calories and days may be transformed into scientiarum materia disciplinae puerilis etsi non scientiae ipsissimae; but for the open air study that aims at tracing the connexion between the hailstone, the lightning flash, the sun's radiation, and the strongth of the blizzard, equivalence and uniformity, if not everything, are at least the beginning and the end of everything; and there is no question that is of more vital importance to meteorology than a system of units with a common measure of energy as its foundation.

NAPIER SHAW.

June 29.

I po not wish to enter into a discussion upon the general subject of units with Sir Napier Shaw, although I believe that my opinion and his do not greatly differ, but I will explain why I profer gram calories per day to watts.

It seems to me that gram calories can be more easily explained to an ordinarily intelligent person than ergs, because the latter require some prior knowledge of dynamics before the explanation can be com-menced. Also the gram calorie lends itself very readily to the expression of the first result of radiation, namely, to changes of temperature; thus by easy mental arithmetic the thickness of ice that can be melted, or of water that can be evaporated, or the change in temperature of a given layer of air is readily calculated. Sir Napier's book is so interesting that it is likely that many people ignorant of dynamics will read it, and I think such readers have a claim to have the difficulties that arise from the inevitable use of technical terms reduced as much as possible.

I agree with what Sir Napier says about the principle of the conservation of energy, excepting that I do not see why it should be belittled by the use of a heat unit as well as a dynamical unit. We commonly use gallons and cubic feet without confusion according to which is the more convenient.

The day as a unit is open to objection, masmuch as there are three kind of days, polar, mean solar, and astronomical, but I think that if the term 'day' used without comment, few would suppose that it meant anything excepting a mean solar day.

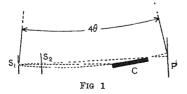

I must confess to having had to look up the definition of a gram calorie in a book of reference, I found three definitions, but they all give the same factor for converting gram calories into joules to the third significant figure, so that the ambiguity in the value of the unit is not at present such as to be of much importance in the measurement of radiation.

W. H. DINES.

#### The Reflection of Atomic Hydrogen from Ice Crystals.

DAVISSON and Germer (NATURE, April 16, p. 558) have shown that electrons are reflected from a nickel crystal in the directions which would be taken by X-rays of wave-length  $\lambda = h/mv$  if they were reflected from a slightly modified crystal lattice. This result, which is in accord with the ideas of L. de Broglie, indicates that the diffractive nature of the reflection is to be associated with the momentum rather than with the structure of the electron. One is therefore led to think that the same phenomenon may exist when atoms are reflected from a crystal surface. Although the investigation of this reflection is not yet completed, the preliminary results support this view and are therefore thought to be of sufficient interest for immediate publication

The experiment consists in finding the intensity of reflection in different directions when a narrow beam of hydrogen atoms strikes a surface of small ice crystals oriented at random. The geometrical arrangement of the collimating slits, reflecting surface, and the detecting plate is shown in Fig. 1. Atomic hydrogen

from a Wood tube is formed into a beam by the slits  $S_1$  and  $S_2$  in a manner similar to that used by Phipps and Taylor (Phys. Rev., 29, 309; 1927). The detecting plate P is also similar to that used by the same authors. The reflector C is a plane polished glass surface cooled by liquid air and covered with a thin coat of frost which, to prevent contamination, is continually renewed by the condensation of water vapour supplied by a suitably cooled side tube containing

The result of a typical exposure is represented by Fig. 2. The shading shows the relative intensities of the hydrogen beams. The lower dark line is the upper edge of the primary beam which passes above C without reflection. The other darkened portions, which are due to reflected atoms, exhibit the following principal features. There is an undarkened band at deflecting angles less than 6° followed by a relatively intense dark band between 6° and 12° which shades off into a uniform darkening at larger angles position of the intense reflected band is not affected by changing the inclination of C from 30' to  $3^{\circ}$  30', but there is a somewhat doubtful change in definition, the line appearing sharper with C set at the larger This point is not quite certain, however, angles. because of a possible illusion due to the difference in the

intensities of various plates. In this regard it is well to point out that if the surface C is placed tangentially to a circle passing through  $S_1$  of such a radius that an arc  $4\theta$ is included between  $S_1$  and P, all specular reflections from the individual crystal surfaces of glancing angle  $\theta$  will come to a focus on PIf the reflected band corresponds

FIG. 2.

to intense reflection at some critical angle between  $3^{\circ}$  and  $6^{\circ}$ , a sharper focus would be expected with C set at  $3^{\circ}$  30' than at any other smaller angle

Calculating the wave-length of the average hydrogen atom at the probable discharge tube temperature of  $400^{\circ}$  C., we find  $\lambda = h/mv = 0.98 \times 10^{-8}$  cm The exact structure of the ice crystal is not well known and still less certain is the nature of the reflection, for it seems reasonable that the surface structure of the crystal should play a more important part than in the reflection of X-rays. If we take 4 3 Å.U. (the probable edge of the unit cell of ice) as the distance between reflecting centres, a wave of the above length should be intensely reflected at a deflecting angle of about 12°, agreeing with the upper edge of the reflected band.

Although more accurate measurements are necessary to establish the exact nature of the phenomenon, it is now quite certain that some sort of a selective reflection is present at small angles. These measurements are being extended, together with an investigation of the effect of the discharge tube temperature on the position of the reflected band. It is also desirable to study the phenomenon with uni-velocity atoms, and it is thought that this may be possible.

THOMAS H. JOHNSON.

Sloane Laboratory, Yale University, New Haven. Connecticut.

#### Biological Fact and Theory.

WITHOUT the slightest hope of modifying or mollifying Dr. Charles Walker's opinions, yet may I point out to readers of NATURE that my previous letter (July 2. p. 12) was not intended to explain or defend in detail the chromosome theory of Mendelian inheritance, as that has been done more or less adequately in every recent text-book dealing with cytology or heredity. I merely directed attention to the fact that this theory is the only one in the field and that it is proving of great service in stimulating biological research. Its value to the student of practical breeding is acknowledged by Prof. Adametz in his "Lehrb. d. allgem. Tierzucht" in the following words: "Die zytologische Begründung der Mendelschen Vererbungstheorie erwies sich, wie im folgenden . . . kurz gezeigt werden soll, von ausserordentlich grossem Wert für das Verständnis verschiedener bis nun wenig verständlicher Vererbungsvorgänge." J. S. DUNKERLY.

#### Past Climates.1

By Dr. G C. Simpson, CB., FRS.

THERE is undoubted evidence that at some period or periods in the earth's history the climate in polar regions was much less severe than it is at present. In the Arctic there are indications of a climate when vegetation similar to that which is now found in subtropical regions flourished in Greenland and Spitsbergen. Geologists have generally supposed that during these periods the temperature over the whole earth was much more uniform than at present, so that the temperature difference between the equator and the poles was very small, if it existed at all These conditions are explained as the consequence of vast oceanic currents carrying warm water to polar regions The Gulf Stream Drift now maintains a mean annual temperature off the coast of Norway in latitude 70° N, which is 10° C. higher than the mean temperature of the latitude, and it is supposed that if its volume,

velocity, or both were increased, and other streams introduced, even higher temperatures could be maintained over the whole of the north polar This supposition is based on an entirely wrong conception of the physical causes which maintain

the existing climatic zones.

The primary cause of the difference of temperature between the equator and the poles is the shape of the earth, which results in higher latitudes receiving less solar energy per square kilometre of surface than lower latitudes. But the distribution of solar energy alone does not determine the temperature at the

surface; if it did the temperature near the poles would fall to near the absolute zero during the long polar winter. During the whole year, especially during the winter, the temperature in high latitudes is governed mainly by the heat conveyed from low to high latitudes by the general circulation of the atmosphere. On the other hand, the general circulation of the atmosphere is caused and maintained by the temperature gradient along the meridians. Reduce this temperature gradient and the general circulation decreases; increase it and the general circulation becomes more active. No one has yet estimated with any certainty the relative amount of heat transported by oceanic currents and by the atmosphere; but whatever the relative amounts, they both depend on the general circulation of the atmosphere, for the heat-carrying oceanic currents are all wind-driven surface currents. Thus, if we reduce the temperature difference between high and low latitudes, we reduce the amount of heat transported by both vehicles.

If a second Gulf Stream were introduced into the northern hemisphere by, say, cutting a wide channel

No. 3014, Vol. 1201

across the middle of Asia similar to the Atlantic Ocean, heat would be carried into the polar basin, where the temperature would rise. But this rise in temperature would diminish the temperature difference between the equatorial and polar air on which the cyclones of the North Atlantic depend The winds associated with these cyclones are, however, the chief vehicle for transporting warm air into, and cold air out of, the polar basin; in addition they are the chief factors in driving the present Gulf Stream Drift along its path. Thus the opening of a new supply of heat to the polar region would be accompanied by a reduction of the old supply and the final result would be little or no change in temperature.

This reasoning is admittedly qualitative and alone would carry no great weight; but the existing temperature conditions are conclusive evidence of

TABLE I.—MEAN ANNUAL TEMPERATURES AT SEA-LEVEL

F - 4 - 4 - 3 -	Average Mean Annual Temperature				Percentage of Land		
Latitude.	North 2	South.	Difference.	Mean. 5	North 6	South 7	Difference 8
0 10 20 30 40 50 60 70 80 90 0-90	°C 26 2 26.7 25 3 20 4 14 1 5.8 - 11 - 10 7 - 18 1 - 22 7 15 2	°C 26 2 25 3 22 9 18·4 11 9 - 4·1 - 13 3	°C. 14 2.4 2.0 2.2 3.3 3.0 2.8	°C 26 2 26 0 24 1 19.4 13.0 5.6 -12 0 (-18.1) (-22.7)	% 22 24 31 43 45 58 61 53 20 0 39	% 22 20 24 20 4 2 0 71 100 100 17	% 4 7 23 41 56 31 - 18 - 180 - 100 22

its correctness. It would be difficult to imagine any distribution of land and sea more different, from the present point of view, than that which exists to-day in the two hemispheres. In the northern hemisphere the land and sea masses are arranged parallel to the meridians, and one ocean extends in an uninterrupted sweep from the equator to the pole; in the southern hemisphere the land and sea masses are arranged parallel to the circles of latitude. Two-thirds of the whole land of the earth is concentrated in the northern hemisphere, mainly about middle latitudes; while the southern hemisphere is mainly occupied by a great ocean which extends almost unbrokenly around the earth between latitudes 40° S. and 70° S In spite of these extremes of land and sea distribution the average mean annual temperature along every circle of latitude, as determined by Meinardus, is practically the same in the two hemispheres, as will be seen from Table I

Space does not allow of one examining this table in detail, but attention may be directed to latitude 70° as being representative of polar regions where one would expect any difference to be especially marked. Within the Arctic Circle there is a great sea; within the Antarctic Circle there is a great

 $<sup>^{1}\,\</sup>mathrm{Abridged}$  from a paper read before the Royal Meteorological Society on June 15.

continent. Outside the Arctic Circle the continents of North America and Asia form together the largest mass of land in any part of the earth; outside the Antarctic Circle a continuous ocean extends completely around the earth for many degrees of latitude. The Gulf Stream Drift, the greatest heat-carrying ocean current which exists, conveys warm water right into the heart of the Arctic Ocean; in the south no current carries warm water within 40° of the pole. Yet there is only a difference of 2° 8 C. between the average temperature along latitude 70° in the north and in the south. In the face of the evidence of Table I. there can be little doubt that the distribution of land and sea

the mean temperature off the coast of Norway being more than  $20^{\circ}$  C. higher than the mean temperature in the west of Siberia

In the zone between 40° N and 60° N, the temperature is highest over the east of the oceans and lowest over the east of the continents. This is due almost entirely to the fact that over the east of the oceans the prevailing winds have a southerly component and over the east of the continents a northerly component. This means that the chief transport of warm air from equatorial regions is over the east of the oceans, and as the winds control the movements of the surface waters the effect of the ocean currents is simply an addition to the

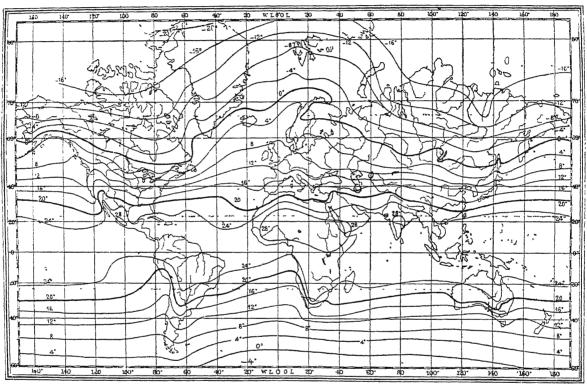

Fig 1 -Yearly isotherms.

plays little part in determining the average temperature along a circle of latitude and that no redistribution of land and water could possibly have raised the temperature in polar regions by the 25° C. required to give Spitsbergen the climate which exists to-day in the Mediterranean.

Although from the above discussion it would appear that the distribution of land and water plays a very small part in determining the average temperature of a zone, there is no doubt that it does play a very large part in determining the actual temperature in various parts of a zone.

Fig. 1 has been reproduced from Hann's "Lehrbuch der Meteorologie" to show the existing variations of mean annual temperature. We see at once that the temperature may be very different at different places along the same circle of latitude. The greatest differences occur along latitude 70° N.,

effect of the winds. On the other hand, the return flow of air from polar regions is mainly over the east of the continents, bringing with it low temperatures from higher latitudes. Whatever the distribution of land and sea within the zone we may expect the same effect, the transport of warm air will be over the east of the waters and the transport of cold air over the east of the land masses. The only question that arises is whether there are any limits to the difference of temperature that may be induced in this way. A glance at Fig. 1 will show that there appear to be such limits. The areas of the continents and of the oceans in the zone we are considering are very different, the extent of Asia being more than twice that of North America and the extent of the North Pacific Ocean being more than twice the extent of the North Atlantic. In spite of this difference of extent the lowest temperature on any latitude over North America is practically the same as the lowest temperature on the same latitudes over Asia. In the same way, in spite of the Gulf Stream Drift the highest temperatures over the North Pacific are very similar to those over the North Atlantic.

The figures are the most striking in the case of the low temperatures in the east of the continents. From latitude 40° N. to 60° N. the great Asiatic land mass produces the same lowering of the

TABLE II

Latitude	Lowest Mean Annual Temperature			Highest Mean Annual Temperature		
	America	Asıa	Difference	Atlantic	Pacific	Difference
°N 40 45 50 55 60	°C 10 6 1 - 5 - 8	°C 8 4 0 - 4 - 8	°C 2 2 1 -1 0	°C 17 14 12 9 8	°C 14 12 9 7 5	°C 3 2 3 2 3

temperature within one or two degrees as is produced by the much smaller North American continent. From this we may conclude that North America is already sufficiently extensive to produce the maximum cooling and that no readjustment of the land masses within this zone would produce lower mean annual temperatures than exist to-day

in the east of North America and in the east of Asia.

Similarly over the sea; when we find that the highest temperatures over the broad North Pacific Ocean are within three degrees of the corresponding temperatures in the narrow North Atlantic with its active Gulf Stream Drift, we may legitimately draw the conclusion that no redistribution of land and water would materially raise the temperature over the sea.

We thus see that in the north temperate zone there are quite definite maximum variations from the mean temperature of the circles of latitude, and that these exist to-day over both North America and Asia. The conclusion is irresistible that at no time in the past could mean annual temperatures exist locally in the north temperate zone which do not occur on the same latitude to-day.

Similar considerations applied to the polar and equatorial zones lead to the same conclusion, and there seems little doubt that

not only have there always existed climatic zones similar to those which exist to-day (assuming no change in solar radiation), but also at no time in the past is a limited region of the earth's surface likely to have had a higher or lower mean annual temperature than can be found somewhere on the same latitude in the northern hemisphere to-day.

## Historical Aspects of Disease.1

INFORMATION regarding disease in the past may be derived from three sources—from human and animal remains in ancient times (a considerably limited field), from a study of old sculptures, models, and pictures, which give more especially evidences of abnormalities in growth, and finally from a study of the medical and other writings of the past. Achondroplasia has been shown to exist in Egypt so early as the Sixth Dynasty (2900 B.C.), and achondroplasic dwarfs are often to be observed in Egyptian mural paintings. Pott's disease of the spine has also been noted in a bronze statuette of ancient Egypt. In a bust of Alexander the Great in his fatal illness, Sir Berkley Moynihan recognised evidences of cerebro-spinal fever. Achondroplasia and rickets are portrayed in the mural paintings of Pompeii and Herculaneum. The portrait of Ferdinand I., Emperor of Germany, painted in 1521 by Lucas van Leyden, shows the adenoid facies, although it was only in 1868 that Wilhelm Meyer of Copenhagen made adenoids known to the medical profession. Hystero-epilepsy has been identified in Raphael's pictures, and Charcot and Richer identified hysteria major and hystero-epilepsy in the engravings of the famous epidemic dancing mania which was prevalent in the Rhine provinces from the fourteenth to the sixteenth centuries Similarly, these authors figured a number of old

pictures showing plague victims with buboes, and among them Saint Roch, the patron saint of the disease.

Paintings may also show diseases which were much more common than at present (leprosy), or conditions which have disappeared from Great Britain as the result of efficient preventive legislation (hydrophobia). Although written records of acute disease are far more numerous than pictures and statues showing pathological conditions, their satisfactory interpretation is much more difficult owing to differences in the methods of description and nomenclature and the possibility of the existence of more than one disease raging at the same time, as was probably the case during the Antonine plague in Rome.

Now disease is not in itself a fixed entity, but the reaction of a complex organism to varying degrees of injurious influences, therefore a change in the organism or a change in the injurious factor may lead to widely different pictures Changes in the organisms responsible for infective disease occur with far greater rapidity than do changes in the higher mammals Some authors consider that changes in the former are much more important than changes in the host Wars and famine readily determine changes in the type of disease by setting up conditions favourable to the spread of disease and unfavourable to the victim of the epidemic spread. Such changes are most liable to occur in the acute diseases, but it is very difficult to decide whether a real change in type has occurred.

<sup>&</sup>lt;sup>1</sup> Abstract of the opening paper in the discussion on "Clinical Variation" in Disease from the Historical Point of View," delivered by Sir Humphry Rolleston to the History of Medicine Section of the British Medical Association at Edinburgh on July 22

Another factor which may alter the clinical picture is the presence of secondary infection, as, for example, was the case in the influenzal epidemic of 1918–19, where the presence of an additional hæmolytic streptococcal infection of the respiratory tract made the condition widely fatal, and so altered the influenzal picture that it was actually hinted in the lay press to be plague. Agam, it has been averred that the more severe type of smallpox was due to the same virus as present in mild smallpox complicated by a secondary streptococcal invasion favoured by insanitary conditions which so often prevailed in the past; but there have been very mild epidemics of smallpox in the past, and along with other evidence it would appear that the mild and severe form are variants of the same virus as is also cowpox. The presence of one disease may sensitise the organism to another infection, as, for example, the influence of measles in leading to tuberculosis.

Other diseases have shown definite changes in type, as in the case of scarlet fever, which forty or fifty years ago was often malignant and now is Other diseases appear to have altered, but in these cases this is often due to a separation out of the disease from a series of closely related conditions, as, for example, the separation out of typhoid, paratyphoid, and typhus from what was formerly known as continued fever It was only in 1675 that smallpox was first clearly distinguished from measles by Sydenham, although an eruption like smallpox was identified in an Egyptian mummy (1100 BC), and chickenpox was not definitely recognised as a distinct disease until 1767. War and its attendant circumstances may also give rise to new types of disease, as, for example, trench nephritis and trench fever, which were seen in North America seventy years before and not during the intervening years. After wars the epidemics and aberrant forms of disease that may have arisen tend to disappear.

The question as to when a disease first appears is one of the greatest difficulties, and may go back before the written records. Tuberculosis has been identified in the Egyptian mummies, and from the written records the pulmonary form was very prominent in Greece Mumps was also known in

ancient Greece. and the orchitic complication described by Hippocrates It may have been plague that attacked the Philistines after their capture of the Ark of the Covenant. Its history can, however, be most certainly traced in epidemic form from the great plague of Justinian which, arising in Egypt Add. 542, spread all over Europe There is good reason to believe that malaria was one of the factors bringing about the fall of ancient Greece and Rome, and the references in classical literature to this disease have been most carefully correlated by W. H. S. Jones His work shows the value of medical history in explaining that of the world

Although gout and rheumatism were only separated in the sixteenth century, chronic arthritis has been shown in neolithic skeletons and in ancient Egypt. Brettoneau separated diphtheria from other throat infections in 1821, although malignant sore throat was described by Aretæus in the second century A.D and by subsequent writers. Cerebro-spinal fever was first recognised in 1805. When encephalitis lethargica was first described in 1917, it appeared as if it were an entirely new disease, but scattered descriptions appear of conditions closely similar even so far back as 1413, when in Tournai there was an outbreak of epidemic hiccup which appears to be a manifestation of the myoclonic form of the disease. Appendicitis existed before it was described by Fitz of Boston in 1886, but it would appear to have become much more common in recent times, while chlorosis has for all practical purposes disappeared. Other anæmias would appear to have increased, or at least are more commonly recognised as a result of improved diagnostic methods.

Environmental factors also determine the incidence of disease, as in the case of parasitic diseases carried by animals or insect carriers, and then in the case of industrial diseases, diseases may have developed, reached a maximum, and then declined as the dangerous features were appreciated and controlled, as happened in the case of trinitrotoluene and tetrachlorethane poisoning. Finally, popliteal aneurism, which was very prominent in persons of a syphilitic taint in the days of horse-riding, has become relatively infrequent with the decline in

use of the horse.

### Obituary.

Prof. J. L. Gustav Tschermak.

PROF. J. L GUSTAV TSCHERMAK—Seysenegg, Hofrat, one of the most distinguished of modern mineralogists and petrologists, whose death was recently announced, was born at Littau, near Olmutz in Moravia, on April 19, 1836. He studied at the University of Vienna, and in 1857, while still a student, he accompanied Julius Schmidt in his examination of the extinct volcanoes of Moravia, and was responsible for much of the field work as well as for the subsequent determination and description of the specimens obtained. In 1858 he published his first paper, which dealt with the trachytes in the neighbourhood of Banov in Moravia. This was the earliest of a long succession

of important publications spread over more than sixty years. In 1861 he was received into the Faculty of Science of the University and acquired the right to give academical lectures. In 1862 he was appointed custodian to the Court collection of minerals.

From 1863 until 1866 Tschermak travelled in the Alps and Carpathians, and as a result published in 1869 a treatise on the porphyritic rocks of the "Middle Geological Epoch" (actually from the Carboniferous to the Cretaceous) in Austria. For this he received an award from the Vienna Academy of Sciences. In 1868 he was appointed Director of the Court collection of minerals, and at the same time was nominated professor of mineralogy and

petrology at the University He retained this post until his retirement in 1906 as emeritus professor and emeritus director of the Mineralogical and Petrological Institute of the University. He was then ennobled as Tschermak von Seysenegg In 1875 he was made a full member of the Vienna Academy of Sciences He was also honorary member of the scientific academies of Berlin, Gottingen, Munich. Paris, Rome, Leningrad and Sweden. He was foreign member of the Mineralogical Society and of the Geological Society of London

The first edition of Tschermak's treatise on mineralogy was published in 1881 and the sixth in 1905. In 1871 he established the Mineralogische Mitteilungen, which formed for a time a portion of the Jahrbuch der Kaiserlich-Koniglich geologischen Reichsanstalt. In 1878 it became the Mineralogische und petrographische Mitteilungen (familiarly known as Tschermak's Mitteilungen), which still continues.

Tschermak's most important work was on the constitution of the silicates. So early as 1865 he published a paper on the felspar group, a synopsis of which appeared in the Geological Magazine for the same year. In this he showed that the plagioclase felspars are built up of varying proportions of albite and anorthite, minerals which closely resemble each other in their crystalline form and in their molecular volumes. This formed the starting-point of Becke's work on the same subject. Tschermak afterwards applied similar principles to the

amphiboles, the pyroxenes, the micas, the scapolites, the chlorites, and the tourmalines, as well as to the rhombohedral carbonates. He also claimed that he could obtain definite silicic acids by treatment of silicates with acid solutions, but this contention has not been universally accepted. He gave considerable time to the study of meteorites, of which a fine collection is housed in the museum at Vienna

Tschermak married Fraulein Hermine Fenzl, who survives him. His two sons hold professorships, at Vienna and Prague respectively.

WE regret to announce the following deaths

Sir William Ashley, emeritus professor of commerce in the University of Birmingham and president in 1907 and 1924 of Section F (Economics) of the British Association, on July 23, aged sixty-seven years.

Sir Bryan Donkin, honorary member of the Royal Medico-Psychological Association, and author of many publications on criminology and related subjects, on July 26, aged eighty-two years.

July 26, aged eighty-two years.
Sir Harry Johnston, G.C M.G., K.C.B.,—zoologist, ethnologist, and explorer—distinguished particularly by his scientific contribution to knowledge of tropical

Africa, on July 31, aged sixty-nine years.

Dr. Paul Kessler, professor extraordinarius of geology at the University of Tubingen, and author of several interesting papers on the morphology of fossil Ammonoidea, on July 14.

Mr. E. Sanger-Shepherd, well known for his work on colour photography and the development of instruments for photographic sensitometry, on July 8, aged fifty-eight years.

#### News and Views.

All large passenger ships have a complete staff of radio operators and keep a continuous watch for radio signals. The great majority of ships, however, have only one radio operator, and so a continuous watch is impossible. Such a ship might be in close proximity to a ship needing assistance and hear nothing of its distress calls. Probably a much larger ship at a greater distance away would be diverted from its course to give the requisite assistance. This would lead to delay and greatly increase the cost. This difficulty has now been overcome by the apparatus designed by the Marconi International Marine Communication Co., Ltd. The object of this auto-alarm is to ensure that the call shall be received by the smaller ships even when the operator is off duty. The alarm signal consists of a series of three dashes, each of four seconds duration, separated by intervals of one second. The Post Office regulations insist that this signal, the forerunner of the distress (S.O.S.) call, shall operate the receiving apparatus, which rings a bell to recall the operator, even when it is sent by hand with the aid of an ordinary watch with a seconds hand. If the signal be wrongly sent, even although the apparatus is set in motion, it will instantly come back to zero and be ready to receive signals correctly sent. Allowances are made for want of skill of the operator by making it operate when the dashes have intervals between three and five seconds long and the blanks have intervals lying between one

fifth and two seconds. The apparatus operates even when two ships are sending Morse messages at the same time and on the same wave-length. When a distress call is received, alarm bells are rung on the bridge, in the radio cabin, and in the operators' sleeping quarters.

SIR RONALD Ross, director-in-chief of the Ross Institute and Hospital for Tropical Diseases, Putney Heath, S.W., has been awarded the gold medal of the African Society in recognition of his valuable work and its services to Africa. In the report of the Ross Institute and Hospital for 1926, recently received, reference is made to the need for extension of the hospital and especially to the importance of the extension of malaria control operations connexion attention is directed to the British Mosquito Control Institute at Hayling Island, and it is suggested that when young men are engaged for service on plantations in the East, it might be advantageous if they could spend a few hours or days at Hayling Island to obtain an idea of the habits of mosquitoes and the methods of control. Sir Ronald Ross was invited by the Indian Tea Association to visit plantations in India and to inspect the work being done there to reduce malaria. He visited also Malaya and Burma, and has prepared a report on his observations. Comparing his experiences while on service in India from 1881-1899 with his recent observations in Ceylon, Malaya, Assam, and Calcutta. he concludes there must be a marked reduction of culicime mosquitoes in the houses of Europeans, due principally to better knowledge of these insects and of their breeding habits, and also to the activities of public health departments. He advocates still further control of both culicimes and anophelines by public action.

MALARIA control in Malaya has reached a high state of efficiency and will quite possibly succeed in practically banishing the disease or at least in reducing the pandemic to small local outbreaks. In Burma, Sir Ronald found that advance has not been nearly so rapid, apparently due chiefly to the fact that the planting community is not nearly so large and there is much more popular, and therefore less instructed, control of the administration. Assam presents a state of transition, the details of malaria control for a large number of estates have been worked out, but the whole movement should be unified in order to prevent expensive local failures due to recalcitrant neighbours and other causes. Calcutta has still much to learn from Singapore; it does not spend enough on mosquito control. Dengue is prevalent every year and malaria still haunts the outskirts of the city The housing of the poorest classes is bad, and Sır Ronald makes an appeal for its improvement by legislation and action. He refers to the formation of anti-malaria and public health societies in Bengal, managed by the people themselves, with many branches in remote villages and rural areas. In conclusion, he remarks that what can be done in other countries against malaria can be done in all. "Is it not time to hope that malaria control by modern methods will soon be adopted everywhere ?"

FURTHER information is now available relating to the remarkable find of a liquid in the canopic jar of Queen Hetepheres, mother of Khufu, which unquestionably has been preserved since the Pyramid age. An analysis has been made by Mr. Lucas, chemist to the Egyptian Antiquities Department, of which some particulars are given in the Times of July 26. It appears that the liquid is a 3 per cent. solution of natron, of which the water has been stained yellow by the organic contents of the canopic jar. It is suggested that the water has been preserved owing to the fact that it was enclosed in an alabaster box with a tight-fitting lid and buried in a chamber cut from the living rock at a depth of 100 ft. and in a niche which had been built up with plaster-covered limestone slabs.

SINCE the resumption of archæological excavation after the War few fields have advanced more rapidly in public interest than Mesopotamia, which at one time was regarded almost exclusively as the province of the specialist. This is to be attributed to a great extent to the broader treatment which has been given to the announcements in the press of the results obtained both by the Weld Blundell Oxford University and Field Museum expedition at Kish and the joint expedition of the British Museum and

the Pennsylvania University Museum at Ur further and welcome indication of this trend is afforded by the publication of a guide to the antiquities of Mesopotamia by Mrs MacKay It deals with sites dating from the earliest period down to, but not including, the Islamic period. For the convenience of travellers the sites are grouped under the stations of the railway from which they are most accessible, and each is described briefly but in sufficient detail to enable the non-expert to grasp the essential significance of what has been revealed by excavation. Brief historical notes, a chronological table from the "Cambridge Ancient History," and a few useful hints on equipment are included. The guide is issued by K. Mackenzie, the Book Shop, Baghdad, Iraq.

FURTHER particulars are announced of the seventeenth International Congress of Orientalists to be held at Oxford from Aug 27-Sept 1, 1928. The president of the Congress will be the Right Hon. Lord Chalmers, and Prof. F. W. Thomas, Boden professor of Sanskrit, will act as chairman of the organising committee. The meetings will be held in the Indian Institute and adjoining College and University buildings. The work of the Congress will be distributed among nine sections, of which one will be general, including anthropology, ethnography, prehistoric archæology, comparative mythology, and folklore. Other sections will be: Assyriology and cognate subjects, Egypt and Africa, Central and Northern Asia, the Far East, India and Iran, including the Indo-European languages of Asia, the Old Testament, the language, literature, etc., of Islam. and oriental art. Each section will have its sectional president. The languages of the Congress will be French, German, and English; but other languages may be used with the permission of the sectional president. The fee for the Congress is £1. Applications for membership should be addressed to the treasurer of the Congress, Mr. G. R. Driver, Magdalen College, Oxford. Titles of papers offered should reach the secretary, Mr. C. N. Seddon, not later than Mar. 1, 1928.

An active eruption of Vesuvius began towards the end of July, and on Aug. I there was a new flow of lava and an increase in the number and intensity of explosions inside the volcano. A large amount of material has been ejected in the form of volcance bombs and ash.

A BRIEF report on the great Kansu earthquake of May 23 (May 22, G.M.T.) has come from Mgr. Buddenbrock, Vicar Apostolic in Kansu (Times, July 30). The writer, who was at Lanchow, the capital of the province, at the time, states that the city of Kulang has disappeared, and he estimates that 100,000 people were killed. Kulang is about 120 miles north-west of Lanchow, and between the positions assigned from seismographic evidence to the epicentre, and nearer to that given by Prof. Turner (see NATURE, vol. 119, pp. 826, 937). According to information received by

the China Inland Mission in London, the earthquake was strong enough to damage buildings so far as Liangehowfu, 150 miles north of Lanchow.

The third meeting of the International Union of Geodesy and Geophysics will be held at Prague on September 3-10. Papers will be read and discussions will take place in the various sections of the Union, namely, geodesy, seismology, meteorology, terrestrial magnetism and electricity, oceanography, volcanology, and hydrology.

DR. EDWARD R. WEIDLEIN, director of Mellon Institute of Industrial Research of the University of Pittsburgh and president of the American Institute of Chemical Engineers, will spend the months of September and October in visits to European educational institutions, research laboratories, and chemical works. While abroad he will also confer with a number of educationists and laboratory directors regarding various problems in industrial research organisation and management. Dr. Weidlein expects to be in England during the period Sept. 14-24, where he may be addressed c/o The Old Colony Club, 79 Fore Street, London. His continental trip through Germany, Switzerland, Italy, and France will follow.

THE ninth International Congress of Zoology will meet at Budapest from Sept. 4-9, under the presidency of Dr. G. Horvath. The offices and the general meetings will be in the Hungarian National Museum, and the sectional meetings will be in the University Institutes of Natural Science and Medicine. A large number of communications have already been offered. In addition to the more serious business, opportunity will be given for excursions on the Danube, to mountains in the neighbourhood, to Lake Balaton, and to the Puszta Hortobágy, with its herds of horses, cattle, and sheep. Various facilities are given by the Government and railways of Hungary. Owing to an unfortunate statement in the preliminary announcement, notices appeared in German zoological publications which made one fear that the Congress would lose its international character; but we understand that any difficulties there may have been are now entirely smoothed away, and a successful gathering, the first since Monaco in 1913, seems assured.

THE fourth Conference of A.S.L.I.B. (the Association of Special Libraries and Information Bureaux) will be held at Trinity College, Cambridge, on Sept. 23-26. The proceedings will open with a reception by Sir J. J. Thomson in the Fellows' Garden of Trinity, and discussions will occupy the mornings and evenings of succeeding days. The subjects for discussion include the following: the Report of the Public Libraries Committee of the Board of Education (Mr. A. E. Twentyman and Lieut.-Colonel L. Newcombe); recent developments in connexion with the Science Library, South Kensington (Sir Henry Lyons); information, organisation, and statistics in industry (Major L. Urwick, Mr. S. J. Nightingale, Mr. Hugh Quigley, Mr. W. Wallace, Mr. A. E. Overton, Mr. F. W. Tattersall); patent classification (Mr. A. R. Wright, Mr. Allan Gomme), problems of the information bureau (Mr A F Ridley, Mr. P. K. Turner, Dr. J C. Withers), photographic reproduction of printed and MS. material (Mr N. Parley, Sir William Schooling, Mr. R H. New); standards of book selection in science and technology (Sir Richard Gregory). Further particulars of the Conference can be obtained from the Secretary, ASLIB., 38 Bloomsbury Square, London, WC1

THE Pacific Hydrobiological Station at Vladivostok was established in 1925 with the view mainly of research on the conditions of the Russian fisheries in the Pacific, but it is working not only on the problems of immediate practical interest, but also on various hydrobiological questions (Priroda, 1927, No. 3). The station is situated at the Basargin Peninsula, about 6 kilometres from Vladivostok, where some old military buildings were converted into laboratories and houses for the staff. During the first year of the existence of the station a systematic study of the marine fauna was begun and regular hydrological observations organised. The fauna of this part of the Pacific proved to be extremely rich, including numerous species of fish not previously known from Russian waters, while the invertebrate fauna is also of unusual interest. Apart from this purely scientific work, a detailed investigation of fisheries in the Bay of Peter the Great and at the Kamtchatka shores was organised. This study revealed that Russian fishing in the Pacific waters is almost exclusively devoted to salmon, while a number of other valuable fish are not exploited only for lack of information as to their valueand methods of fishing. Laboratory accommodation at the Station is calculated not only to permit scientific work of its own staff, but also to enable outside students to work there temporarily.

THE seventh annual report of the Industrial Fatigue Research Board gives an account of its constitution. investigations, and researches. Its work roughly falls into three main categories: (1) Investigations of particular problems of wide industrial importance, such as hours of labour, accident causation, design of machinery, ventilation, rate of improvement in industrial occupations, vocational guidance, the relation of school-leaving age to well-being and proficiency. (2) Studies of specific problems submitted by government departments and industrial associations, e.g. sickness in cotton-weaving sheds and in the printing industry, weight carrying by men and women, telegraphists' cramp, vision and lighting, vocational selection. (3) Experimental researches undertaken in university and other laboratories, e.g. principles governing muscular energy, acquisition of skill, psycho-galvanic reflex. The Board directs attention to the necessity for a more general realisation of the possibilities and necessity for such research which, while its immediate effects may be less striking than those resulting from technical and mechanical developments, yet has far-reaching effects valuable both to the worker and employer. For example, an alteration in some material condition may lead to an increased

output immediately: if, however, that alteration should put too much strain on the workers, then increased sick-leave or general dissatisfaction may result, the effects of which will only be gradually felt. The Board suggests that small committees representing employers and workmen should be set up in the more important industries for the purpose of discussing and submitting for investigation problems affecting the human factor in industry

In the May issue of the journal of the Allgemeine Elektrizitats Gesellschaft an account is given of a lecture by Dr. Lubowsky on the transport and packing of engineering products for foreign markets. This subject is of the greatest importance to industry and deserves close study. At the beginning of the War, the Germans made many tests, using suitable machinery, to find out the stresses called into play by every conceivable method of packing, the amount of packing material required, and the space taken. It is sometimes specified that the apparatus ordered should be contained in a soldered sheet tin case without stipulating on the methods requisite for the adjustment between the external and internal atmosphere. These are essential on account of the variations of temperature and atmospheric pressure A small accident to a soldered edge often leads to the collection of condensed water in the box. This may arise also from the hygroscopic nature of the goods. Drying chemicals will not prevent the bad effects produced by condensation. The A E.G. have found that hard wood cases suitably dove-tailed and utilising pitch-paper and oil-cloth are cheaper and much more serviceable. When there is a risk of breakage the goods are suspended by spiral springs during transport. In order to ascertain their weakest points, cases and casks were periodically allowed to fall to the ground from given heights. Thus particulars have been obtained for nearly every class of wood as to the requisite thickness, best method of stiffening, number, strength, and distance apart of the bands, best length and finish of the nails, appropriate humidity, and many other useful data.

WE referred incidentally in a recent issue to the educational experiment being made at the Malting House School at Cambridge, which aims at stimulating and developing the 'finding-out' interest in children from the age of 4-5 years onwards. A film privately exhibited by the school a week or so ago in London illustrated the methods used. The children, mostly between four and seven years of age, were shown finding out for themselves the properties of things. the sequences of various processes, the relations between objects, and between their own activities and these objects. They were shown trying whether leaves would burn, whether metals would melt, or how much water would put the fire out; a see-saw led them to try to weigh one another, and then to weigh and compare various objects on a balance, the water-tap in their sandpit went out of order and one of them tried with a spanner to turn it; some of them modelled in clay or used a potter's wheel; others listened to a gramophone, managed by them-

selves; they were shown taking care of their live pet animals, and dissecting ('looking inside") dead ones, they handled well and truly hammer, nails, chisel, a large saw, a drilling machine, a lathe; they sewed and wove; and moving freely in and out of these and other interests, they enjoyed, not less but not more, imitation and phantasy games, running about and climbing, like any other lively children of their ages. As one watched the ease and independence with which the children went about their manifold activities, it could scarcely be doubted that whatever additional methods practical educational needs might impose, all that children learned by this method is so much clear and certain gain.

THE Bureau of Standards at Washington publish a directory of commercial testing and college research laboratories. Apparently there are 207 commercial testing laboratories throughout the United States and no less than 143 college research laboratories. These form a most useful adjunct to the National Bureau of Standards, the main object of which is to make tests and carry out investigations for other government departments. The other laboratories do the ordinary routine work, and so the Bureau has more time to devote to research and official work. In Great Britain, engineers have standard specifications which they are continually revising, but the number of institutions which are prepared to test whether the material or workmanship comes up to the standard is very small and is practically unknown to many purchasers, and hence they hesitate to buy on specifications and trust too much to a firm's reputation. The Bureau of Standards has inaugurated a 'certification plan.' On this plan, lists of manufacturers are compiled who are willing to supply material in accordance with certain specifications and to guarantee that they fulfil the required conditions. We know of certain clauses in several widely used specifications which are virtually a dead letter in England, because very few purchasers know where they can get the required tests made, and even when they do, the prices are found to be prohibitive. In the immediate future there will probably be a great increase in the demand for such tests both in connexion with our domestic and our export trade. In our opinion a directory similar to the one produced by the Bureau of Standards in America, giving a list of both commercial testing and college research laboratories, would be a boon to industry in Great Britain.

The following awards for the year 1927–28 have been made by the Salters' Institute of Industrial Chemistry and approved by the Court of the Company: Fellowships renewed: Mr. R. M. Deanesly, University of Oxford, at the Ramsay Department of Chemical Engineering, University College, London (Fellow, 1926-27); Mr. H. B. Spalding, University of Oxford, at the Massachusetts Institute of Technology (Fellow, 1926-27). Fellowships awarded: Mr. C. G. Akhurst, Imperial College of Science and Technology, London; Mr. A. Caress, University of Cambridge; Mr. I. G. Nixon, University of Cambridge; Mr. D. R. Pryde,

University College, Bangor, Mr. J. Muir Smith. Armstrong College, Newcastle, Mr. F. Witt, Imperial College of Science and Technology, London. The Salters' Institute has also awarded fifty Grants-in-Aid to young men employed in chemical works to facilitate their further studies.

THE Japanese meteorological observatory at Zinsen, Tyosen (Korea), has just issued a very comprehensive report of its activities during the year 1923. Hourly values are given of air pressure and temperature, relative humidity, and wind speed and direction, at the central observatory, while four-hourly observations of various meteorological elements at the observatory and its branch stations, which are numerous, are summarised. Details of the seismic and (absolute) magnetic observations made at Husan and Zinsen are also included. The work appears to be well organised, and the report is detailed and satisfactorily produced. The letterpress is given in Japanese characters and also in English. The customary European symbols for cloud forms and other meteorological phenomena are replaced by picturesque Japanese symbols, which by no means convey their import to a European reader at a glance.

REFERRING to the review which appeared in NATURE of July 16, p. 76, of Gurwitsch's "The Scientific Principles of Petroleum Technology," Prof. B. N Menschutkin, of the Polytechnic Institute, Leningrad, writes pointing out that Prof. Leo Gurwitsch died on May 30, 1926.

The National Research Council, Washington, D.C., has issued through its Committee on Child Development a "Directory of Research in Child Development" (Reprint and Circular Series, No. 76, Price 50 cents). The entries, 425 in number, give the names of research workers in the United States and Canada, the subjects of their specialties, and the research problems upon which they are engaged.

WE have received from Mr. C. Baker, 244 High Holborn, W.C.1, and Messrs. Ogilvy and Co., 20 Mortimer St., W.1, their respective catalogues of second-hand and shop-soiled scientific apparatus for sale at reduced prices. Prospective purchasers would do well to consult these catalogues in the first place, for many bargams in microscopical and other apparatus, cameras, etc., are listed.

Messes. Flatters and Garnet, Ltd., 309 Oxford Road, Manchester, have sent us their catalogue of microscopical preparations (Catalogue A, 1927). They claim to be the largest actual mounters of microscopical preparations in England, and their normal stock of mounted slides numbers 25,000-30,000. The list is a very complete one and comprises preparations illustrating all the biological sciences as well as petrology and metallurgy.

THE Edinburgh Mathematical Society has begun to issue a new series of its Proceedings. An attractive opening part contains ten research papers, Profs. Baker and Turnbull and Mr. Richmond being among the contributors. A general reader will find most interest in Prof Gibson's "Sketch of the History of Mathematics in Scotland to the End of the Eighteenth Century." This paper gives an account of the mathematics studied in Scottish universities in their early days, and refers especially to the work of Napier and of James and David Gregory. It is unfortunate that a standard size of page has not been adopted for the new venture, also that the pages are not numbered in the customary place.

The British Museum (Natural History) has added four sets of picture post cards to the two issued last year illustrating native British orchids. The various species are beautifully and faithfully done in colours, and the price of each set (F 16 to F 21) is one shilling, each consisting of five cards with an explanatory leaflet. Thirty out of some fifty known British species are represented in the six sets so far published. Many of them are uncommon, and some very rare and in danger of extinction. One aim of the Natural History Museum postcards of British flowering plants is to protect rare species by indicating the fact of their rarity and by providing a ready means by which unknown plants may be identified without picking them.

The Proceedings of the South London Entomological and Natural History Society for 1926-27 forms an attractive booklet of more than 150 pages with several half-tone plates. It contains a number of short papers which should appeal more especially to Thus Mr K. G. Blair discusses entomologists. stridulation in various orders of insects, while Dr. E. A. Cockayne writes on intersexes in Lycanida, and Mr. R. Adkın has a suggestive article on the possibility of new species being in the making in the case of certain British moths. The reports of the meetings of the Society indicate that its members take a live interest in various branches of natural history and botany, and the exhibits recorded cover a wide range in those subjects.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned :- A fulltime lecturer in mining science and allied subjects under the director of education, Merthyr Tydfil, for the instruction of students in the higher stages of the joint scheme of education adopted by the L.E.A.'s in the South Wales and Monmouthshire coalfields-The Director of Education, Town Hall, Merthyr Tydfil (Aug. 9). A secretary for education for the Borough of Widnes-The Town Clerk, Town Hall, Widnes (Aug. 15). A highly qualified assistant at the East Malling Research Station, to abstract reports of a scientific nature—The Secretary, East Malling Research Station, East Malling, Kent (Aug. 15). A bacteriologist for the Dairy Research Laboratories, New Zealand - The High Commissioner for New Zealand, 415 Strand, W.C.2 (Aug. 23). An assistant lecturer in zoology in the University of Birmingham-The Secretary, University, Birmingham (Aug. 24). A junior assistant in chemistry in the agricultural department of the Marischal College, Aberdeen-The

Secretary, North of Scotland College of Agriculture. 41½ Umon Street, Aberdeen (Aug. 27). A professor of zoology in the University of Manitoba—The Registrar, University of Manitoba, Winnipeg, Manitoba, Canada (Sept. 1). An assistant lecturer in botany and zoology at the University College of Swansea-The Registrar, University College of Swansea, Singleton Park, Swansea (Sept. 5) An assistant lecturer in electrical engineering at the Manchester Municipal College of Technology—The Registrar, College of Technology. Manchester (Sept. 19). Two lecturers, in biology and chemistry respectively, in the University of Western Australia—The Agent-General for Western Australia, 115 Strand, WC2 (Oct. 1) A head of the department of building of the Manchester Municipal College of Technology—The Registrar,

College of Technology, Manchester (Oct 3) senior demonstrator in the department of physiology of the University of Otago, Dunedin, New Zealand -The Registrai. University of Otago Dunedin. New Zealand (Oct 20) An assistant in the department of physiology and brochemistry of University College. London-The Secretary, University College, Gower Street, W.C.1 A temporary assistant bacteriologist for research on fabrics in Admiralty Establishment-The Secretary of the Admiralty (CE. Branch), Whitehall, S.W.1 An agricultural botanist at the Seale-Hayne Agricultural College-The Principal, Seale-Hayne Agricultural College, Newton Abbot, Devon. A laboratory assistant in the zoological laboratory of the University of St. Andrews-Prof. D'Arcy W. Thompson, The University, St. Andrews.

#### Our Astronomical Column.

NAKED-EYE SUNSPOTS.—A large circular or 'regular' spot has recently been in transit across the sun's disc. This is the second appearance of the spot which began its existence more than a month ago in the previous 10tation. Its area measured on July 25 was a little more than 500 millionths of the sun's hemisphere, which is about the limit at which spots become nakedeve objects to keen evesight. Owing probably to its regular outline, the spot was seen without difficulty by several observers Particulars of its position are given in the table below, including another spot, No 6, which was on the disc about a month ago. This spot was seen on one or two days only, partly on account of unfavourable weather, but as its area exceeded that of the more recent spot, it has also been tabulated Spot No. 6 represents the third and last appearance of a naked-eye group whose earlier history is given in Nature, May 21, p 759, and June 18, p. 903.

Central Meridian Latitude Passage. No. Date on Disc. Area. July 5.4 July 27.8 June 29-July 11 15° N 1/1500 s° ŝ 1/1900 July 21-Aug. 3

SPECTROSCOPIC PARALLAXES OF EARLY TYPE STARS. The spectroscopic method of determining parallaxes was at first confined to stars of later type. It is considerably more difficult to apply it to types A and B, and it is necessary to use sharpness of spectral lines as a criterion, and further to employ different standards of sharpness for each subdivision of spectral type. Two papers describing researches on this subject made at the Norman Lockyer Observatory appeared in *Monthly Notices of Royal Astronomical Society* for March. The first, by D. L. Edwards, applies various tests to the method of Adams and Joy and gives curves connecting the line-character with absolute magnitude for types  $B_0$  to  $B_9$ . These curves are then used to deduce parallaxes for 300 stars. The resulting parallaxes are compared with those by other authorities and found to be somewhat smaller, the

mean difference being about 0 002".

The stars of type  $A_0$  to  $A_5$  are dealt with in a paper by Dr. H. C. Woods.

The classification is chiefly by the sharpness of the hydrogen lines, and is tested by trigonometrical and group-motion parallaxes. This list also contains 300 stars. The deviations in individual stars from the trigonometrical or groupmotion values are considerable in stars with peculiar spectra, but generally small for the others.

The stars in both lists are naked-eye stars contained

ın Boss's P.G.C.

VARIABLE ROTATION OF THE EARTH —Prof. W. de Sitter investigates the fluctuations in the motion of the sun, moon, Mercury, and Venus in Bull. Ast. Int. Netherlands, vol 4, No 124. He adopts from ancient observations the secular acceleration  $+\,1''\,\,80$  for the sun and +5'' 22 for the moon, noting that the ratio of the former to the latter is too high according to the ordinary theory. He finds that the accelerations of the sun, Mercury, and Venus are proportional to their mean motions, as they should be if produced by tidal friction. the moon alone is discordant. He suggests that the secular acceleration of the moon may itself be variable. Taylor and Jeffreys found that the friction occurs almost entirely in shallow seas, where they would be liable to slow changes owing to silting up, etc. Accordingly, the acceleration in modern times (which is the one determined for the planets and partially for the sun) may be different from that determined for the moon, which depends on ancient observations. The changes in the earth's rotation are concluded to be of two kinds: one due to tidal friction, supposed to be variable, the other due to changes in the earth's moment of inertia.

Prof. de Sitter thinks it better to treat the great empirical term in the moon's motion in the same manner as the smaller terms — It is not safe to assume that either of them follows sine curves; they can be as well represented by a zigzag of straight lines. He notes that his results from Jupiter's satellites are not in harmony with those from the sun, Mercury, and Venus. He suggests that the Jovian system may have fluctuations of its own.

A METEOR TRANSITS THE SUN.—Astr. Nach. No. 5505 contains a note by A. Stentzel of Hamburg, describing an observation of the transit of a round black object, some 18'' in diameter, across the sun's disc from P A.  $120^\circ$  (about) to  $5^\circ$  (about), on Mar. 15 at  $15^\mathrm{h}~25^\mathrm{m}~\mathrm{U}~\mathrm{T}$ . The time of passage was 6 seconds. The object was sufficiently distinct to make certain that it was not a distant bird The observer notes that it is the first undoubted observation of the kind that he has made in twenty-seven years of observing. A very similar transit across the moon was noted by Dr. W. H. Steavenson, a few years ago, and described in the B.A.A. Journal. The rate of apparent motion was about the same in each case. The slowness of the motion makes it probable that the distance, and therefore the size, of 'the object were considerable. Most meteors cross the telescopic field in a small fraction of a second.

#### Research Items.

Edinburgh Folklore —In the Nineteenth Century and After for July, Mr. Lewis Spence publishes the first instalment of a much needed study of the folklore of Edinburgh. He proposes to deal with his study under three heads: (1) Mythology, dealing with traditional material predominantly of a religious character. (11) legendary tradition related to human personages or persons once actually existing; and (m) folklore associated with ritual, popular customs, or superstition. In the first section he shows that the Chapel of St. Triduana in Restairig was in all probability originally a structure erected over a holy well serving as a place of immersion. The shrine with its holy well was a resort of pilgrims for the cure of blindness. St. Triduana is not in the Roman calendar and was probably a Celtic goddess who, on account of the similarity of the legend accounting for her blindness, is to be equated with St. Brigit, the goddess Brigantia of the Brigantes, and Sulina (Gael. Suil, "eye of life"), worshipped at Bath. Brounger, associated with the fishing suburb of Newhaven in popular tradition, was an old fisherman who when he did not fish himself asked for a few fish or oysters from his returning neighbours. If they refused, ill luck followed. He is equated with the thunder god through a tradition connecting him with a flint or meteorite suggesting the holy or lucky stones representing that deity. It is possible that he may be Perunu, the thunder god, of Rugen, linking up through the connexion of the North German fishers with Scotland, and also the Slavonic Bog. A demon, Shellycoat, finds an analogy in Japan only, and a piper who disappeared in a subterranean passage from the Castle to Holyrood recalls the legend of Orpheus and other stories of that class.

A NEW VIEW OF PILTDOWN MAN.—In Man for July, Prof. Frassetto of Bologna figures and describes his reconstruction of the jaw of Piltdown man, which he compares and contrasts with the jaws of the orang and the chimpanzee. In his view its resemblance lies in the direction of the orang rather than that of the chimpanzee. He gives in tabular form eight points m which the orang differs from the chimpanzee, and in which the jaw of Piltdown man, so far as its condition allows, is comparable with it. As a whole the jaw of the chimpanzee is relatively thin, slight, and light, while both orang and Pıltdown are massive and heavy; the ascending ramus is oblique in relation to the horizontal portion, but in the orang and Piltdown almost vertical; the position of the semilunar notch coincides in the two jaws, but in both differs from its position in the chimpanzee jaw; the angle has a curvature of a large radius in orang and Eoan-thropus, but it is small in the chimpanzee; the posterior margin of the chimpanzee ramus is narrow to the root of the condyle, where it widens rapidly, but in both the other jaws it widens gradually as it passes into the condyle. Again, the lower borders of the corpus of the mandible resemble one another in both orang and Piltdown but differ from the chimpanzee, which also has a relatively small genual fossa as opposed to the large fossa of the other jaws. The reconstruction was therefore made by grafting the symphysian region of the orang's mandible duly enlarged on to the corpus of Piltdown man's jaw, the conclusion being that the jaw is human, belongs to the same individual as the cranial fragments, and represents a primitive race belonging to a genus of the orang type. Not only is this because of the features of the mandible, but also because of the eyebrow ridges, which do not exhibit the prominent torus characteristic of the climpanzee type to which Neanderthal man belongs.

INDUSTRIAL PSYCHOLOGY ON THE FARM.—The National Institute of Industrial Psychology, in Report No. 2, records the results of an investigation into certain processes and conditions on farms undertaken by Mr. W. R. Dunlop. The results would seem to show that farm management in Great Britain is by no means efficient. It is unfortunate that so many discussions on agricultural problems are complicated by political motives. The present investigation is the first systematic attempt in Great Britain to apply the point of view and methods of industrial psychology to agriculture. Two problems were studied (a) the picking and packing of truit, including bush fruit, hops, and glass-house produce, and (b) milking. shown that the best pickers at one kind of fruit are the best pickers at all other kinds, that there is no evidence to show that atternoon rates are lower than those of the morning, that there are considerable individual variations in efficiency. The milking problems include discussions of milking rates, differences of cows, manual skill of milkers. Some very important questions are raised in the third section dealing with future enquiries, not the least of which is the selection of the right worker for the right work. and the guidance of young people leaving school into occupations for which they are most fitted. Apparently there is a tendency for the children of a lower level of intelligence and ambition to take up agriculture, the town attracting the more intelligent. In so far as this is so, it is to be deplored, but obviously the problems connected with such a choice are very difficult to attack, involving as they do the attitude of mind of the community towards agricultural work, the lower standard of nominal wages and the ties with regard to hours.

THE SCIENCE OF ROWING.—Among the papers read at the July meeting of the Institution of Naval Architects at Cambridge was one on "The Propulsive Efficiency of Rowing," by Mr. F. H. Alexander. In welcoming the Institution to Cambridge the Vice-Chancellor, the Rev. G. A Weekes, spoke of the subject of rowing as of particular interest to Cambridge men, especially as it is a matter of controversy at the present time. There are two schools of thought, the old orthodox school and a new school, which has proved very successful over short courses. Mr. Alexander's paper recorded the results of investigations as to the magnitude of the forces employed by oarsmen and the utilisation of those forces, a racing 'eight' and a ten-oared whaleboat being chosen for consideration. Various tables were given showing dimensions, ratios, properties of hull forms, weights of boats and crews, amplitude of the movements made by the crews, the oars and the boats, together with the speeds at different points of the stroke. It will come as a surprise to many to learn that the power developed amounts to so much as  $1.09\,\mathrm{H.P.}$  for each man in the 'eight' and  $0.90\,\mathrm{H.P.}$ for each man in the whaleboat. The efficiency of the total work in an 'eight,' re the ratio of the work done per minute by resistance (91,800 feet-lb.) to the total work performed by the crew (288,680 feetb.) works out at 0318. In the whaleboat the efficiency is only 0221. The paper was accompanied by diagrams, and some of the points raised in the discussion will be dealt with by Mr. Alexander in a written contribution to the Transactions.

Cancer in Europe.—Prof. Eugene Pittard of Geneva contributes an interesting article to the World's Health for June (vol. 8, No. 6) on the distribution of the incidence of cancer among the anthropological races of Europe. Surveying Italy, France, Holland, and Switzerland, the fact seems to emerge that the Nordic race is more prone to be attacked than the Celtic, Mediterranean, and Adriatic races. The last named, which includes the northern Albanians, the Bosmians, Montenegrins and others, seems almost immune from cancer.

THE PARASITOLOGY OF PLAGUE.—In regional studies in the parasitology of plague (Ceylon Jour. Sci., vol. 1, Part 5, 1927) Dr. L. Fabian Hirst remarks that the gradual recession of plague from Europe at the end of the seventeenth century is one of the mysteries of epidemiology Undoubtedly the substitution of the long sea route to the east round the Cape of Good Hope for the journey via the Mediterranean and the overland routes must have played an important part. But, he reminds us, bubonic plague is a disease of rats and the human epidemic is a mere offshoot of the epizootic, and therefore the fact which most requires explanation is the disappearance of the disease among the British rats and its failure to spread continuously when reintroduced among them. The generally accepted theory that the disappearance of plague from Britain is to be attributed to the replacement of the black rat (Rattus rattus) by the brown rat (R. norvegicus) is unsatisfactory, for the cessation of epidemic plague does not coincide with the appearance of R. norvegicus in England—it had been extinct for a generation when (in or about 1728) the brown rat reached England. The conditions prevailing in the wooden dwellings of old London with their large contents of grain, combined with defective scavenging and tolerance of large colonies of rats living in close association with man, amply suffice to explain the intensity of the historic human epidemics which devastated the city at fairly frequent intervals prior to the great fire. The former London plague season— June to December, with maximum prevalence in August and September-corresponds to the period of greatest prevalence of the flea Xenopsylla cheopis in Marseilles and Lisbon at the present day. climatic conditions during plague years seem to have been especially suitable for the breeding of X. cheopis; during the great epidemics of 1636 and 1665 the summer was exceptionally hot and dry. That the disappearance of plague from Britain and Europe generally may possibly be due to a retraction of the area of X. cheopis prevalence is compatible with the

ANTS OF THE CANARY ISLANDS .- In Proc. Amer. Acad. Arts and Sci., vol. 62, April 1927, pp. 93-120, Prof W. M. Wheeler contributes an interesting paper on this subject. He visited each of four of the larger islands during July and August 1925 and was able to collect and observe a considerable proportion of the ants known to occur in the Archipelago. He lists 56 species, subspecies and varieties now known, and by far the greater number have been taken in Teneriffe, the other islands having been little explored by entomologists. Nearly 70 per cent. of the total ant fauna is indigenous to the Canary Islands, while of the remaining forms, twelve are well-known south European and north African insects and five are tropicopolitan species Among the latter the most important is the Argentine ant, Iridomyrmex humilis. Prof. Wheeler mentions that the banana plantations are suffering severely from this pest. Fear of closing the European markets to their produce has prevented the officials from announcing its presence, and Prof. |

Wheeler states that he encountered it in enormous numbers on three of the islands visited. This ant does not attack the banana directly, but owing to its fondness for honeydew excreted by coccids it not only cultivates these sap-sucking insects on the foliage but also transports their larvae from plant to plant

BUTTERFLIES OF SAMOA.—The Trustees of the British Museum have recently undertaken the publication of an account of the Insecta and other terrestrial Arthropoda collected in the Samoan Islands during 1923–24 by Dr. P. A. Buxton and Mr. G. H. E. Hopkins. The material collected was obtained during the expedition of the London School of Hygiene and Tropical Medicine to the South Pacific. The monograph will be divided into eight parts, which will be subdivided into fascicules. latter will not appear in serial order, each one being published as soon as completed. On completion of the work it is intended to issue an introduction, summarising the whole monograph, and drawing from it whatever conclusions as may be warranted. The first study to be issued is Part 3, Fascicule 1 (London: British Museum (Natural History), 1927. 58. Maps No. 1, South-West Pacific; No. 2, Samoan Islands. 6d), dealing with the butterflies of Samoa and of neighbouring island-groups, by Mr. G. H E. Hopkins. It is noteworthy that with the exception of the comparatively recent American immigrant, Danaida archippus, the butterflies inhabiting Samoa and the neighbouring groups of Islands are all Indo-Malayan in origin. Most of them are widely spread through Polynesia and appear to have reached Samoa by way of Fiji.

LIVING CELLS UNDER DARK-GROUND ILLUMINATION.-The late Dr. T. S. P. Strangeways and Dr. R. G. Canti employed dark-ground illumination for the study of the living cell in culture and of the effects of fixing reagents upon the constituents of the cell. (Quart. Jour. Micr. Sci., vol. 71, Part 1, 1927). Cultures of the choroid and sclerotic, heart, kidney, intestine, and skin of the embryonic fowl were em-When growing on the surface of the covership the cell is flattened, has an irregular 'feather-like shape, and shows no true cell-wall, the outline being apparently caused by reflection from the interface between the cytoplasm and the surrounding culture medium. This outline is unceasingly changing, if the culture is observed in the warm incubator, and the cell wanders over the surface of the coverslip by slow amœboid movement. Cells so observed show no nuclear membrane or Golgi apparatus. The centrosphere is seen as a cap over one side or end of the nucleus. The mitochondria appear to be formed in this region and to wander therefrom into the clear cytoplasm. Chromosomes can be distinguished in a dividing cell, but the most careful scrutiny failed to reveal a trace of spindle-fibres. The principal changes produced by fixing reagents were the formation of precipitate in nucleus and cytoplasm and shrinkage of these, distortion or destruction of the delicate cytoplasmic processes resulting in the cell assuming an artificially regular outline, the fusion of adjacent fatglobules, the modification or disappearance of the mitochondria, and the appearance of spindle-fibres in the dividing cell. Of all the reagents tested, 2 per cent. osmic acid produced the least change in the cell. The authors also describe the destructive effect of strong light (from the dark ground condenser) upon cells which had been fixed in a reagent containing chromic acid. The entire cell, with the exception of the fat-globules, was completely dis-

REDIA AND CERCARIA OF FASCIOLA.-W. Rees Wright records (Ann Trop Med. and Parasit. 21, 1927) observations on the redia, cercaria, and cyst of Fasciola hepatica. Thomas's statement that the sporocyst and daughter rediæ are not to be found during late summer and autumn is confirmed; at that time of the year, reduce produce cercarize only. The redia is cylindrical and about 2 mm. long and 0.4 mm. in diameter; its wall is very thin-for the greater part of its surface it is only one cell thick. Delicate muscle fibres, longitudinal and transverse, appear to be present in the wall external to the principal layer of cells. In addition to the simple digestive system there is an excretory system consisting of numerous flame-cells and their ducts, the main groups of flame-cells being near the oral end and near the two processes of the body wall, as Thomas pointed out. The redia, as Thomas indicated, is not a passive parasite, Wright states that in the case of very thin-shelled snails the rediæ may be seen devouring the liver tissue and moving through it Wright describes and figures the position of the seven pairs of flame-cells of the cercaria. The cercaria emerge from the parent redia through the birth pore, find little resistance to their movements in the eroded visceral mass, and escape from the snail through the respiratory aperture. Experiments with encysted cercaries in artificial gastric and duodenal fluids suggest that complete digestion of the cyst walls takes place in the duodenum and not in the stomach. There is no definite evidence to show that Limnæa truncatula is the only intermediate host of Fasciola hepatica in Britain; observations are cited which suggest that L. peregra may also act as intermediate

Non-Marine Mollusca of the Belgian Congo.-During the years 1909-15 the American Museum of Natural History maintained an exploring expedition in the Belgian Congo, under the leadership of Mr. H. Lang. The scientific results of that expedition, so far as the general invertebrate zoology was concerned, were published in the Museum's Bulletin, vol. 37, while a "Review of the Land Mollusks" by Dr. H. A. Pilsbry appeared in 1919 (Bull. Amer. Mus. Nat. Hist., risbry appeared in 1919 (Bull. Amer. Mus. 1746., 1746., vol. 40, art. 1). Now, at long last, there comes to hand the companion volume on "The Aquatic Mollusks... With a geographical and ecological account of Congo Malacology" by Dr. H. A. Pilsbry and Dr. J. Bequaert (Bull. Amer. Mus. Nat. History, and Dr. J. Bequaert (Bull. Amer. Mus. Nat. History, and Dr. J. Bequaert (Bull. Amer. Mus. Nat. History, and St. 1919. vol. 53, art. 2). A bulky volume of 534 pages and 68 plates, with numerous text illustrations, it forms with its predecessor a complete monograph on the malacology of the vast territory of the Congo basin from the Atlantic coast to the great lakes of Central Africa, and will undoubtedly prove the standard book on the subject for many years to come. It is not to the malacologist alone, however, that the work will appeal, for the section on the zoogeography and ecology of the area will interest the general zoologist, and even the botanist and geologist. seems to have been most thoroughly discussed and is well illustrated, text maps are furnished of the whole continent giving orographical details, rainfall, faunal areas based upon the distribution of birds, the hypothetical distribution of lake and river basins towards the close of the Pleistocene period, as well as other charts more immediately germane to the special Twenty-two of the plates, moreover, are devoted to most excellent views of various habitats. The one defect of the whole work, and it is a big one, is the lack of any index. The Museum would do well if it would devote some future number of its Bulletin to an index to both volumes, and so crown what is a most important and valuable work.

NEW AMERICAN AND WEST INDIAN MOLLUSCA. Dr. Paul Bartsch has described some new species of West American marine Gastropoda (Proc. U.S. Nat Mus vol. 70, art. 11), mostly small representatives of the Tænioglossa and Gymnoglossa. The thirty-one species believed to be new, with some previously species believed to be new, with some previously described by the author but not figured at the time, are illustrated on six plates Mr. W. B. Marshall contributes a short paper (*Proc. U. S. Nat. Mus.* vol. 71, art. 6) on "A New Genus and Two New Species of South American Freshwater Mussels." The new genus, Mycetopodella, has been created for the recention of the remarkable elongated form of Unio originally described under the name of Mycetopus falcatus Higgins, but since successively described to several other different genera. The new species are Anodontites guanarensis and Mycetopoda pittieri. Dr. H. A. Pilsbry (Proc. Acad. Nat. Sci. Philad. vol 79) describes Ceratodiscus portoricensis, n sp., a small land mollusc from Porto Rico. The genus has hitherto been known by one species in eastern Cuba and another in western Hayti, so that the new discovery extends the range of this peculiar group eastwards.

Earthquakes in Norway.—The earthquakes of Norway have been studied from the year 1887, and m a recent paper (Bergens Museum Aarboh, 1926) Prof. C F. Kolderup has described those of the years 1924 and 1925. This was a period of unusual infrequency, the yearly numbers being 5 and 8, and also of slight intensity, for only one shock disturbed an area of more than about 1500 square inless. During the twenty-five years 1889–1913, 479 earthquakes were felt in Norway and 358 in Great Britain. Thus, taking the areas of the two countries into account, the frequency of earthquakes in them is almost identical, the ratio being 385 for Norway to 394 for Great Britain.

Microdissection.—The issue of Watson's Microscope Record for May (No. 11) contains matter of considerable interest. Dr. Eric Ponder contributes an article on 'microdissection,' in which by means of fine needles carried in mechanical holders minute structures, such as protozoa and cells, can be dissected while being viewed by the microscope, and any particular element, such as the nucleus, removed. The method is comparatively new and has many possibilities. Mr. G. T. Harris contributes Chapter III. of his studies of the Desmidiaceæ and Mr. W. G. Royal-Dawson details for mounting pollens for the microscope.

DISTANCE THERMOMETERS.—Messrs. Siemens Bros., Woolwich, have just issued a revised list of electrical distance thermometers. Amongst the instruments described are some designed to meet the special requirements of refrigeration, and they reflect the influence of the scientific workers studying problems of refrigeration on the design of technical apparatus for industrial use. One thermometer is intended for use in the refrigerated holds on board ship, and by means of flexible metallic connexion may be fixed in position or removed in a few moments The object is to obtain an accurate measurement of the temperature of the cargo itself, which may differ considerably from that of the air near the refrigerating pipes. Another installation illustrated is a special outfit for a large precooling plant in South Africa. This is fitted with switch gear for connexion to 149 thermometers. In addition, five anemometers are fixed in the air ducts and five anemometer counters are fitted on the top of the board. Another installation which is illustrated was made for a grain elevator plant and was fitted with 900 thermometers.

#### Plankton of the Gulf of Maine.

THE great importance of the small and microscopic animals and plants that drift throughout the water layers in the sea and constitute the 'plankton' is now well established. On the plankton plants, chiefly consisting of diatoms, most of the animal life in the sea is ultimately dependent for its food supply. It is therefore natural that in fishery investigations, when seeking the basal causes of fluctuations in supply of fish, much time should have been spent in a study

of this drifting life.

For the past twenty-five years the European countries attached to the International Council for the Exploration of the Sea have carried out extensive programmes in the regions of the great sea fisheries, no small part of which have been concerned with plankton research. The course of such investigations naturally follows an evolutionary path, and, while the earlier years were spent in classifying the various species and noting their comparative abundance and distribution in different localities, the work is now tending to a more detailed and minute study of those few forms that have been proved, on account of their numbers and prevalence, to be of the greatest importance in the economy of the sea.

Such is the position on the European side of the North Atlantic, but research is not so far advanced in the western Atlantic along the American seaboard. It is only in a recent publication <sup>1</sup> that full details of the preliminary survey necessary to depict the general characters of the plankton, and to point out those species worthy of a more detailed study, are forth-

coming.

The area dealt with in this report is the Gulf of Maine, the oceanic bight from Nantucket on the west to Cape Sable in Nova Scotia on the east. The survey has been very thoroughly carried out and brings out clearly the major fact that the characteristics of the plankton community are essentially the same as those long known to be the case in other boreal

waters of the North Atlantic.

The report, which has been written by that distinguished American oceanographer, Dr. Henry B. Bigelow, is divided into two main portions, the first dealing with the animals of the plankton and the second with the plants. The outstanding feature of the animal plankton is the predominance of the small crustacean copepod Calanus finmarchicus. This small creature is indeed deserving of a wider appreciation by the public, as it forms one of the main articles of food that constitute the links in the chain between plankton plants and fishes. Its abundance is over-awing to the human mind, suffice it to say that in his largest eatch Prof. Bigelow obtained upwards of 2,500,000 individuals by towing a net with a circular opening of one metre diameter through the sea for fifteen minutes. This huge catch shows that the region under observation can hold its own with the richest waters on the eastern side of the Atlantic, the largest catch the present writer is aware of being recorded by Hjort in "The Depths of the Ocean, p. 726, namely, at least 2,000,000 in a ten minutes' haul with a similar net to that mentioned above. Prof. Bigelow gives an instructive chart which emphasises clearly the predominance of this crustacean over other animals in the plankton.

In the catches also appear, in smaller and varying numbers, several species that characterise the collections, notably the copepods *Metridia lucens* 

<sup>1</sup> "Plankton of the Offshore Waters of the Gulf of Maine. By Henry B Bigelow Bulletin of the Bureau of Fisheries, vol. 40, 1924, part 2, Document No. 968, pp. 1-509. Washington, 1926.

and Pseudocalanus clongatus, the 'glass-worm' Saguta elegans, the amphipod genus Euthemisto, the euphausid genera Thysanoessa and Meganyctiphanes; the pteropod Limacina retiorersa, the ctenophore Pleurobrachia pileus, and in deeper water the large copepod Euchæta These organisms are here together designated the 'Calanus community.' Mention should be made of the euphausiid group; these shrimp-like animals are of considerable size compared with the other members of the plankton, Meganyctiphanes reaching a length of an inch or more, and their importance as food for fishes is being increasingly realised. There are few fish from northern waters, indeed, that have not been found feeding on them, and they form the chief food of the whalebone whales, the distribution of which in the Norwegian Sea has recently been shown by Hjort in a preliminary survey (Cons. Intern. pour l'Explor. de la Mer, Rapp et Proc. Verb, vol. 41, 1927, p. 115) to coincide at times with that of Meganyctiphanes. In this connexion Dr. Bigelow gives two interesting photographs of the fringe of whalebone plates, showing how the coarser fringe of the fin-back whale (Balanoptera physalus) allows the smaller animals of the plankton to pass through, the larger organisms, such as the euphausids, alone being retained, while the fine fringe of the bone of the pollock whale (Balænoptera borealis) is able to retain in addition large quantities of the copepod Calanus.

Besides the species mentioned above, all animals present in the collections are dealt with in detail in the report as regards their seasonal and regional distribution. In the work of identification the author received the assistance of Prof. C. B. Wilson, but although relieved of this labour, Dr. Bigelow's report must represent the results of a vast amount

of careful thought and study.

In dealing with the plants, or phytoplankton, for identification of which the author was indebted to Dr. Albert Mann, it is evident that far less information was available than in the case of the animals. Nevertheless, it is sufficient to show that in their general trend of behaviour the plants follow the same course in their seasonal distribution as they do in European waters. There is a very abundant plankton of diatoms in early spring which dies down and is succeeded in the summer months by a less abundant

peridinian plankton.

At the end of this second portion of the report, Dr. Bigelow gives a valuable discussion on the problems connected with the cycle of events characteristic of phytoplankton throughout the seasons, in which a summary of much of the modern literature on the subject is included. The importance of those possible limiting factors in the environment, such as phosphates, nitrates, and silicates, is discussed, but the reader is left with the realisation that much work must be carried out before the various phenomena can be thoroughly understood. Unfortunately, no work on the phosphate and nitrate content of the sea-water comparable to that of Atkins and Harvey at Plymouth, and more recently Marshall and Orr at Millport, has yet been carried out in the region under survey.

Dr. Bigelow is to be congratulated on producing an addition to the literature that will prove invaluable to many plankton workers. The report is illustrated with many beautiful photographic plates reminiscent of those produced by the school of marine biologists at Port Erin, and contains an extremely useful bibliography of 365 titles.

F. S. R.

### Engineering and Technological History.1

THE desirability of preserving and making readily accessible accurate and authoritative information regarding the rise and decay of industries, the development of tools and machines, the evolution of handicrafts, and the lives of the principal actors therein, can scarcely be disputed. With the passage of time mines are abandoned, factories pulled down, machines and tools scrapped, papers are dispersed, and the pioneers often forgotten. Even when manuscripts and drawings are preserved, it is frequently difficult to learn of their whereabouts, and the student is often at a loss to know where to look for original material.

In its efforts to further the study of engineering and technological history by the preservation and publication of such information as that referred to, the Newcomen Society is doing valuable work and has gained for itself a recognised place among the technical societies of Great Britain. The fifth volume of its Transactions is evidence of the wide scope of its activities and the high standard of the matter presented. The present volume contains the papers read before the Society during the session 1924-25 Glass-making, the art of the gunsmith, the windmill in America, the evolution of the boring machine, the Eddystone lighthouses, are among the subjects dealt with. Two other papers on the iron industry of Coalbrookdale bring into proper perspective and correct date the epoch-making work of the Darby family, five generations of which engaged in iron smelting and founding. Both Mr. J. W. Hall and Mr. T. A. Ashton write on this subject, and the latter concludes his review of the work of the Darby family with the following pregnant paragraph: "The first Darby used coke m place of charcoal in the production of castings;

<sup>1</sup> The Newcomen Society for the Study of the History of Engineering and Technology Transactions, Vol. 5, 1924-1925 Pp Ni+139+22 plates (London Newcomen Society, Science Museum, 1926.)

his son converted this coke-smelted iron into malleable iron with charcoal; the Cranages and Henry Cort substituted coke for charcoal in the final process. By so doing they broke the last shackle binding the industry to the woodlands and enabled it to renew its youth on the coalfields of the Midlands, Yorkshire, and South Wales The work begun by Abraham Darby in 1709 was completed by Henry Cort in 1794."

Among other contributors may be mentioned Mr. C. E. Greener, whose knowledge of guns and gunmaking is unrivalled; Sir Flinders Petrie, who illustrates a discourse on ancient glass in Egypt by three plates giving specimens of Egyptian glass before 1200 B c., between 1200 and 300 B c, and between 300 B c. and A.D. 300, Mr. D Brownlie, who recalled a neglected worthy, John Patison of Airdrie (1828–1905), a pioneel in the shale oil industry, while Mr. R Jenkins annotates some letters of the elder

Brunel on boot-making by machinery

A word should be said about the bibliographies that have appeared in the Transactions. Vols. 2 to 4 contained parts of a bibliography of engineering and applied science, compiled by Mr. E. W. Hulme. Most of the items given referred to articles published in periodicals and journals of the last few years. In the present volume is a subject list of books and pamphlets relating to the history of technology published during the period 1920-25. There are several hundred items in the list, which has been compiled by Mr. A. Gomme, of the Patent Office Library, and the value of the list is increased by the insertion of an asterisk against such of the books as are to be found in that library. We trust these bibliographies will be continued, and thus a body of information accumulated which will be of value not only to writers and students of engineering history, but also to others concerned with biography, economics, and commerce.

## Appeal for the University of Sydney.

In its comparatively brief existence of seventy-five years, the University of Sydney has been the recipient of numerous private benefactions. The princely Challis bequest (1880) of £276,000, and the even greater munificence of the late Sir S. McCaughey (1920), have rendered the University much less dependent than its neighbours upon State aid, particularly as the income in each of these instances is available for general purposes. Other noteworthy gifts, including one of £100,000 by Sir P N. Russell, and another of £30,000 by Thomas Fisher, were allocated to specific purposes by the donors.

Such benefactions must doubtless be numbered among the chief factors which have brought about a development so rapid that the University "now finds itself in a more critical position than ever before, . . . its resources have not kept pace with its requirements." This quotation is taken from a pamphlet which has been issued recently by the University authorities under the title of a "75th Anniversary Appeal" for further funds. According to the facts set down therein, the University of Sydney, with an enrolment of 2490 in 1925, must be included among the major universities of the Empire. The teaching staff, however, numbers only 217; on the Liverpool scale itshould be increased to 364, and on the Manchester scale to 452. A further handicap is discerned in an exhibition system which exempts 200 undergraduates per annum from fees, for a maximum period of 5

years, in return for a yearly Government grant of £20,000. Since, in addition, all teachers and intending teachers are entitled to a similar remission, there were 1084 students in 1926 who paid no tuition fees. The fees payable by other students average £25 per annum in the Faculty of Arts and nearly £40 in the Faculty of Medicine.

The Government of New South Wales has been liberal in granting a sum of about £50,000 per annum over a period of several years for the provision of newbuildings, in strengthening existing departments, and in establishing new ones. The creation of new chairs, however, seems to have contributed considerably to the mounting expenditure. Owing to the adoption of the Workers' Compensation Act, the rise of wages, and the increased number of employees, the payments for attendants and laboratory assistants have risen by £7777 since 1922. Thus, although nominally wealthier, the University is relatively poorer, and in spite of a general services fee of a guinea a term which has been levied, not without protest, on every student, the present year will probably close with a deficit of some £8000.

Meanwhile, many claims press for fulfilment in connexion with (1) grounds, roads, and buildings, (2) sport, (3) the library, and (4) maintenance and research. The new chemistry building is still incomplete, pathology, pharmacy, and psychiatry are inadequately accommodated; the additions to the

最終後年の高いりからい ハイング

library are unfimshed; and "the University grounds give the impression of shabbiness and neglect." Further, the McCaughey Research Fund of £1000 per annum, from which grants were formerly made to teachers and graduates of the University, has been in abeyance since 1923. At the present time, apart from the question of future expansion, it is estimated that an additional revenue of more than £12,000 per annum is needed to enable the University to discharge all the functions that properly belong to it.

The University of Sydney, though young in years, is rich in achievement. Australia suffers from no lack of public-spirited citizens, and we hope that this appeal from one of the greatest centres of learning in the southern hemisphere will evoke an adequate response.

### University and Educational Intelligence.

CAMBRIDGE.—Mr. L. E. S. Eastham has been appointed lecturer in advanced and economic entomology

Mr. L. H Wilson, Emmanuel College, has been elected to the E. G. Fearnsides research scholarship on the organic diseases of the nervous system.

Dr E. H. Minns, fellow of Pembroke College, has been elected Disney professor of archælogy.

LEEDS.—The Court of the University has decided to confer the following honorary degrees on the occasion of the meeting of the British Association in Leeds in September next,—Doctor of Laws (LL D.): Sir Arthur Keith, president of the British Association; the Duchess of Atholl, and the Hon. Sir Charles Parsons. Doctor of Science (D.Sc.): Dr. J. S. Haldane, Dr. N. V. Sidgwick, Dr. F. O. Bower, and Dr. R. A. Millikan, of the California Institute of Technology, Pasadena. Doctor of Philosophy (Ph.D.): Mr. James Graham.

London.—The following doctorates have been conferred. D Sc. in botany on Major T F Chipp (Birkbeck College) for a thesis entitled "The Gold Coast Forest: a Study in Synecology"; D Sc in chemistry on Mr P. B. Ganguli (University College) for a thesis entitled "Studies in Colloidal Chemistry." Mr. E. S Hedges (Bedford College), for a thesis entitled "Periodic Electrochemical Phenomena." and Mr. S. J. Lewis (University College), for a thesis entitled "1. The Ultra-Violet Absorption Spectra of Blood Sera. 2 The Ultra-Violet absorption Spectra and the Optical Rotation of the Proteins of Blood Sera. 3. A New Sector Spectrophotometer": D.Sc in physiology on Dr. A. S. Parkes (University College), for a thesis entitled "On the Occurrence of the Oestrous Cycle after X-ray Sterilisation"; D.Sc. in zoology on Mr. C A. Hoare (London School of Hygiene and Tropical Medicine), for a thesis entitled "Studies on Coprozoic Chlates"; D.Sc (Engineering) on Mr. A C. Vivian (Imperial College (Royal School of Mines)) for a thesis entitled "The Preparation and Purification of Beryllium."

It has been resolved to institute an Academic

Diploma in Biology.

The title of reader in philosophy in the University has been conferred, as from September, on Miss L. S. Stebbing, in respect of the post held by her at Bedford College. Miss Stebbing studied at Girton College, Cambridge, and at King's College, London. Since 1924 she has been lecturer in philosophy at Bedford College, London. Her published work includes "Pragmatism and French Voluntarism" (Camb. Univ. Press, 1914), and numerous articles in Proc. Aristot. Soc., Mind, and other philosophical journals.

MR GEORGE F O'RIORDAN, Principal of the Leicester College of Technology since 1924, has been appointed Principal of the Battersea Polytechnic in succession to Dr R H Pickard, who has accepted the post of Director of the British Cotton Industry Research Association.

A SENSIBLE Heat Distillation, Ltd., Coal Research Fellowship at the Imperial College of Science and Technology is being offered to candidates possessing a first-class university degree with chemistry as principal subject and intending undergoing two years' research training leading to industrial work in coal carbonisation. The value of the fellowship is from £175 to £200. Applications must reach the registrar of the College by Aug. 31.

From the National University of Ireland we have received its Calendar for 1927, a bulky volume of nearly a thousand pages. A summary of examinations at the constituent and recognised colleges in 1926 gives the following total numbers of students examined: at University College, Dublin, 1236; Cork, 525; Galway, 242; St. Patrick's, Maynooth, 166. Candidates admitted to the degree of B.A. were: Dublin, 92; Cork, 36, Galway, 7, Maynooth, 74. The other degrees granted were chiefly medical (146), commerce (63), and science (56). Four valuable travelling studentships (£200 a year for two years) were awarded in economics, experimental physics, modern languages, and agriculture, respectively.

A PAMPHLET on "Education in the United States," prepared under the direction of the Commissioner of Education for the Pan-Pacific Conference, 1927, has reached us. Its twenty-five pages provide a very useful summary, concise but comprehensive, of the organisations concerned with education in that country of all grades from kindergarten to university and the various types of adult education. The statistics are elucidated by interesting comments on recent developments. The traditional demarcation between the elementary and the secondary or high schools tends to give place to the 6-3-3 plan, consisting of six annual grades above the kindergarten followed by a three-years junior high school (for pupils of from 13 years to 15 years) which, in turn, leads to a three-years high school (ages 16 years to 18 years). This is designed to meet the special needs of the years of adolescence and to afford, especially for those who are not destined to complete the high school course, a better preparation for life than is possible under the old 8-4 scheme About one secondary school in every six is now organised according to the newer plan. Among other recent developments noticed are: school consolidation, or the uniting of several small schools in one, which is proceeding at the rate of one thousand a year; consequential schemes for the transportation of pupils at public expense amounting now to more than thirty million dollars annually; the increase since 1920 in the proportion of men teachers in elementary and secondary schools; advancement of professional requirements for teaching; extended use of the 'project' method in teaching; co-operation of pupils' parents; increase in industrial and trade courses in secondary schools; municipally supported colleges and universities; adjustment of college entrance requirements with the aim of selecting the more gifted students; junior colleges offering the first two years of work of the ordinary four-years college; approximation of standards for all colleges and universities.

### Calendar of Discovery and Invention.

August 7, 1807.—The famous Bell Rock Lighthouse, which was begun on Aug. 7, 1807, and completed in 1811, was the greatest work of Robert Stevenson. Modelled after Smeaton's Eddystone tower, it is 112 feet high and 42 teet in diameter

August 8, 1793.—Founded by Colbert in 1666, the Paris Academy of Sciences with similar institutions on Aug. 8, 1793, was suppressed by the Committee of Public Safety. Two years later, however, saw the founding of the Institut National des Sciences et des Arts.

August 9, 1831—The first locomotive that ever ran on commercial service in the United States was the Stourbridge Lion, built at Stourbridge, England. The most famous of early American passenger engines, however, was the De Witt Clinton, which on Aug 9, 1831, ran from Albany to Schenectady, a distance of 17 miles, attaining a speed of 30 miles an hour.

17 miles, attaining a speed of 30 miles an hour.

August 10, 1675.—The founding of a Royal Observatory by Charles II. was due to the representations of Flamsteed, Sir Jonas Moore, Sir Christopher Wren, and others. Various sites were considered, but at Wien's suggestion Greenwich Hill was chosen. The warrant for the building was dated June 2, 1675, the first stone was laid on Aug. 10, and eleven months later Flamsteed took up his residence in the observatory. Towards the building the King gave £500, while some of the bricks came from Tilbury Fort.

August 10, 1846.—The famous Smithsoman Institution of Washington came into being by an Act of Congress approved on Aug. 10, 1846. James Smithson, the founder, an illegitimate son of the 1st Duke of Northumberland, died at Genoa in 1829, leaving a fortune of more than £100,000 to a nephew for life, and then to the United States of America, to found at Washington, under the name of the Smithsoman Institution, an establishment "for the increase and diffusion of knowledge among men." The motives which actuated Smithson will probably never be known, for practically all his personal papers were destroyed in a fire in January 1865. Smithson was buried in the English cemetery at Genoa, but in 1904 his remains were removed from Genoa and now rest in a small chapel in the Smithsoman Institution.

August 11, 1716.—In the London Gazette for Aug. Il-14, 1716, an advertisement appeared to the effect: "Whereas the invention for raising water by the impellant force of fire, authorised by Parliament, so lately brought to the greatest perfection . . . as is demonstrated by diverse engines of this invention now at work in the several counties of Stafford, Warwick, Cornwall, and Flint . . . if any person shall be desirous to treat with the proprietors for such engines, attendance will be given for that purpose every Wednesday at the Sword Blade Coffee House in Birchin Lane, London. . . ." This is probably the earliest advertisement of the Newcomen beam engine, the oldest of all practical steam engines.

August 11, 1877.—It was on the night of Aug. 11, 1877, that Asaph Hall, with the large telescope at Washington, first caught a glimpse of one of the small satellites—Phobos and Deimos—of Mars. A few days later he was able to observe both satellites.

August 12, 1851.—Numerous as were the inventors of sewing-machines, it was Isaac Merritt Singer who made the first practical machine and also achieved commercial success. Singer's patent was dated Aug. 12, 1851, and the well-known firm bearing his name was founded in 1856. By 1863 the sales numbered 21,000 annually; by 1878, 350,000; by 1896, 800,000; while to-day the number has grown to between two and three million.

#### Societies and Academies.

#### DUBLIN.

Royal Dublin Society, June 28.—J Reilly and (i. Pyne· A modified micro-method for the determination of molecular weights. This depends on the alterations in the cooling curve of pure camphor produced by minute amounts of dissolved substances. The method is particularly useful for substances the low solubility of which in camphor, or their high molecular weight, precludes the use of the ordinary Rast method.—J. Wilson: Lord Morton's quaggahorse hybrid. Was it a hybrid?

#### Edinburgh.

Royal Society, June 20.-T. J Jehu and R M. Craig. The geology of South Harris In the Archæan complex are two well-marked bands of paragnesses which include crystalline limestones, quartz-schists, graphite-schists, garnetiferous sillimanite-gneisses, and garnetiferous kyanite-gneisses. With these are associated hornblende-schists and gneisses and hornblende-pyroxene rocks which are probably of igneous origin These appear to be the oldest rocks in the district. Between the bands is an intrusive igneous complex ranging in character from an anorthosite-gneiss to a gabbro-diorite and eclogite. Belonging to the same period of intrusion are ultrabasic bands found in various parts of the island. The north-western part of the area is made up of a granite-gneiss which sends tongues and bands into the neighbouring rocks, and associated with this granitegneiss are abundant pegmatites Along the eastern margin of South Harris there is evidence of crushing and shearing with the formation of mylonites at places—Robert Campbell and J. W. Lunn: Tholentes and dolerites of the Dalmahoy syncline. An account of the petrology of a suite of cognate intrusions associated with the Cementstone group and the Lower Oil Shale group of the Scottish Carboniferous. The rock types represented are basalts, tholeines, and dolerites all closely related to mugearites and essexites. They contain favalite of late crystallisation associated with primary quartz, and are noteworthy also for their richness in chlorophæite. They are regarded as hypabyssal equivalents of the mugearitic and other They are regarded as alkali basalts of Lower Carboniferous age found at Corston Hill and elsewhere in the Edinburgh district.

—Cyril Crossland: Marine ecology and coral formations in the Panama region, Galapagos, and Marquesas Islands, and the atoll of Napuka. The three regions described are sharply contrasted in climate, geology, flora, and fauna. Panama and the islands off its coast have a littoral fauna of great richness, but an extraordinary absence of alge. In the Galapagos alge abound, Sargassum in places giving the shores a temperate rather than tropical appearance. There are small coral flats in the Panama islands, but these are made of one species of Pocillopora, are unconsolidated, and would be thrown on to the beach in any sea of less continual calm. No coral deposits were found in the Galapagos (pace Agassiz), but considerable quantities are thrown upon certain beaches. The absence of reefs round the Marquesas has often been remarked. The coral fauna is greatly restricted, only five genera with twelve species being present, so that the problem is, after all, one for the biologist. These species belong to the Indo-Pacific fauna, not to that of the eastern side of this ocean. There are no true reefs in the group, the nearest approach to one being a structure which is probably unique. It consists apparently of one huge colony of a massive Porites, and therefore the whole reef has

grown from a single ovuin. In the atoll of Napuka an ancient reef flat was found about two feet above the present sea-level, and the actual reef is an erosion flat, a foot or so above the present level of growth. It appears to be undergoing destruction by the sea — W. G. Thomson: On the discharge of a condenser through a gas at low pressure. Observations were noted of the flash which frequently occurs in a discharge tube at low pressure when the electrodes are connected with the terminals of a charged condenser. Photographs of single flashes were shown. Spectrograms of the flash were obtained in air and in hydrogen. The former consisted mainly of lines of the spark spectrum of air, while in the latter, many lines of the second spectrum were identified.—E L. Ince: Researches into the characteristic numbers of the Mathieu equation (in)

#### IPSWICH.

Prehistoric Society of East Anglia (at the Royal Anthropological Institute), May 24.—J. E. Sainty: Acheulean flaking site at Whitlingham, Norfolk Report on excavations on behalf of the Sladen Trust Few palæolithic implements have been recorded from the Norwich district, but this site, discovered by the author and Mr. H. H. Halls, was exceptionally prolific. 550 artefacts were recovered in all, including 173 hand-axes. The implementiferous deposit was part of the 50-foot terrace of the River Yare. An upper clayey loam yielded sporadic specimens showing Le Moustier technique: one large end scraper of grey flint being of the well-known "High Lodge " character. Sterile ferruginous sand, stony gravel, and shelly sand underlay the Moustier horizon and separated it from a bed of gravel one to three feet thick, about eight feet below surface, which proved to be the main implement-bearing horizon. implements show little if any sign of abrasion; several are of large size and range from  $10\frac{1}{2}$  inches in length downwards. Species of Chellean character, heavily abraded and striated, are also present and point to an ice advance between the period of that culture and the time of the Acheulean industry .-J. Reid Moir: Report on excavations at Hoxne made on behalf of the British Association and Sladen Trustees in 1924 and 1926. The results obtained confirmed the main facts observed in the British Association Committee researches conducted by Clement Reid in 1895-96, and produced important new evidence. The lacustrine beds of Hoxne rest in an ancient basin eroded in the surface of the Kimmeridgian Boulder Clay, and the implement-bearing horizon is later than the arctic plant-bed which overlies the 'temperate' clays filling the bottom of the basın. These lower deposits appear devoid of human artefacts, but St. Acheul hand-axes occur in thin gravel seams at the base of the brick-earth which covers the arctic plant-bed. The implements are slightly rolled and agree with those illustrated in Frere's classic paper of 1797, so that the gravel in question was probably the source of the implements which he reported upon. In the brick-earth itself, above the gravel, traces were found of a 'floor' of early Le Moustier date with hand-axes of black unrolled and unchanged flint. The early Le Moustier brick-earth is in turn sealed in by a contorted material of glacial origin containing 'erratics' and broken and striated implements of various ages down to that of Le Moustier; the deposit itself being correlated with the Upper Chalky Boulder Clay of East Anglia. The interglacial age of the lower palæolithic industries of St. Acheul and early Le Moustier times is thus taken to be established for this region and the second interglacial stage of East Anglia is indicated.—Miss Layard: A late

palæolithic settlement in a river terrace of the Colne, Essex. Numerous small flake implements occur at depths varying from 11 it. to 2 it in water-laid gravels. They strongly resemble the more familiar continental cave industries of this period, and are fashioned out of pebbles rather than mined flints. The unrolled condition of the flints and the numerous cores found indicate a settlement. Small hearths have also been discovered Characters belonging to both Aurignacian and Magdelenian work are noticeable. At the same time there are certain original characteristics which may be provincial. The occurrence of some more or less celt-like tools, in close connexion if not belonging to this industry, makes it probable that they should be placed at the very end of the Upper Palæolithic period, and it has been suggested that they approximate most nearly to the Maglemosean culture. A fine feuille de laurier of undoubted Solutrean workmanship was also discovered in a lower stratum of the same section -H. F. Dowie: Further excavations in Kents Cavern. In the second season's excavations the removal of six feet of cave-earth underlying the stalagmite floor revealed fints and fauna similar to those from above it. Three human teeth discovered have been stated by Sir Arthur Keith to be Upper Palæolithic. The flint implements discovered last year have been variously regarded as Middle and Late Aurignacian. No palæolithic hearth or workshop, or any surface definable as a 'floor,' has been discovered. Re-sortment and mixture of deposits has probably occurred owing to flooding. The recent reclassification by the Abbé Breuil of harpoons of Magdalenian 6, results in placing the uniserial specimens with trapezoidal barbs found in the upper levels in 1866, at the very end of that period, and they are further stated to be Maglemose types. The brachycephalic skull found at Kents Cavern is similar to skulls found in Aveline's Hole, and possibly at Cresswell, which seem to appear first in Great Britain in a milieu of Late Magdalenian implements in bone and horn and a flint industry with survivals of Late Aurignacian types and a tendency to geometric forms.—S. Turner Report on discovery of worked flints at Stone Cross Farm, Luton, Kent. A considerable number of white patinated flints apparently of palæolithic character, including one definite ovate hand-axe, were found. They were battered, and indicated much exposure. They occurred in a patch of gravelly material which had been covered by about six feet of clay-with-flints. The cultural affinities of the specimens are problematical and their characters peculiar.

#### PARIS.

Academy of Sciences, June 27.—Marcel Brillouin: The field of exterior gravitation and densities in the superficial layer of the globe. The question of isostasy.-H. Douvillé: Some episodes in the formation of the Pyrenees.—Gabriel Bertrand and D. J. Perietzeanu: The relative proportions of potassium and sodium in plants. The amounts of potassium in the fresh plant, in the dry material, and in the ash are given for 35 species of plants. The ratio potassium/sodium for the same plants is also given, this ratio varying from 1040 to 1.15.-A. Blondel: A method of synthetic discussion of the conditions of working of steam turbine governors.-Paul Helbronner: The common sides of the Avignon parallel and the southern chain of the French Alps. A discussion of the accuracy of the geodesic networks connecting the Lake of Geneva with the Mediterranean.—Leonardo Torres Quevedo was elected an associé étranger in succession to the late Kamerlingh Onnes.—E. Cartan: Certain remarkable Riemann forms

of geometries with a simple fundamental group.—L. Feraud A generalisation of the point correspondences which establish projective applicability - Maurice Gevrey: Problems at the limits of the elliptic type; the case of contours with angular points —M Lavrentieff. A problem of P. Montel —D. S. de Lavaud The fundamental critical velocities of a motor-car. —Robert Esnault-Pelterie: Methods and apparatus for the measurement of Hertzian hardness. The Hertz definition presupposes a transparent and brittle body: the author uses a modified definition which is applicable to opaque bodies, and especially to hard The hardness is measured by the pressure  $p_m$  at the centre of circle of contact of two equal spheres of radius r=1 at the moment when the diameter of contact ceases to follow the law of Hertz  $d=1.761 \stackrel{3}{\sim} \overline{Fr/E}$  (F in kilograms, r and d in em., E in kilograms per sq. cm.). Two methods of carrying out the experiment are described and data given for quartz and for various steels.-Raoul Ferrier: The two magnetic moments of the atom A discussion of the effects of the discordance between the Bohr moment (M) and Weiss moment (M')—Félix Michaud: Binary mixtures of volatile liquids. The case where the molecules of one of the components are partially associated.—Ny Tsi Ze: The electrical deformations of quartz.—C. Mihul: The structure of the second order spectrum of carbon (C II).—Maurice Auméras: The conductivity of hydrofluoric acid. A repetition of W. Ostwald's experiments on the electrical conductivity of hydrofluoric acid, with special care in the purification of the acid, gives values for the constant k lower than that of Pick  $(7\cdot2\times10^{-4})$ .—A. Sanfourche and B. Focet: The decomposition by water of monocalcium phosphate (CaH<sub>4</sub>(PO<sub>4</sub>)<sub>2</sub>. H<sub>2</sub>O).—Paul Bauret, Albert Portevin, and Pierre Chevenard: Alloys suitable for resisting the effects of an alternating temperature gradient and, in particular, alloys suitable for fine glass moulds .-Mile. M. Quintin: A relation between the activity of the hydrogen ions H<sup>+</sup> and that of metallic cations in a solution of salts of the heavy metals. It is shown that in solutions of the sulphates and nitrates of zinc, cadmium, and copper, the activity of the metallic ion is, for all concentrations between M/2 and M/2048, proportional to that of the ion H+.-P. Vaillant · The rôle of the intensity of the maximum absorption in the displacement of Kundt.-Jacques de Lapparent: The hydrated alumina of bauxites.—F. Dienert: The sources of the alluvial water of the Loire valley.-M. Lenoir. The observation of the pollen kinesis in living Lilium candidum. These observations on the living specimen show that the hetero-homeotypical scheme, established from the study of fixed and stained preparations, is perfectly exact.—M. Bridel and Th. Aagaard: The diastatic hydrolysis of turanose. Turanose is not hydrolysed by emulsin, rhamnodiastase, or the autolysate of high yeast, but low yeast causes the rapid hydrolysis of this glucoside. This is not due to the sucrase present but to an active  $\alpha$ -glucosidase. Turanose is a glucoside of fructose. - Marcel François and Henri Piéron: Sensations of apparently internal heat are of cutaneous origin (experiments by the diathermal method).—Raymond-Hamet: The splenic vasomotors.—H. Hérissey: The extraction of asperuloside from Galium verum. The probable presence of this glucoside in numerous plants of the Rubiaceæ family.—E. Aubel and L. Genevois: The oxidation-reduction potential of yeast, of Bacterium coli, and of the media in which these micro-organisms increase. - J. Cantacuzène and O. Bonciu: Some peculiarities relating to filtered scarlatina products.—J. Giaja, X. Chahovitch, and A. Giaja: The absence of fever in the rat deprived

of the suprarenal capsules Rats after removal of the suprarenal capsules suffered no temperature rise when inoculated with a culture of the pyocvanic bacıllus

#### CAPE TOWN.

Royal Society of South Africa.—April 20: M. R. Levyns . A prelumnary note on the Rhenoster bush (Elutropappus Rhinocerotis) and the germination of its seed. Under natural conditions the Rhenoster bush has no power of reproducing itself, its spread is largely due to man's influence, veld-burning being an important factor.—William Adam Jolly: On some defensive reflexes. The reflexes obtained in the hind limb of Xenopus on stimulation of one or both feet are discussed.—E. Newbery: Note on overvoltage prob-Modern improvements show that transfer resistance is a real quantity and therefore that the direct method of measuring overvoltage is incorrect. These improvements are mainly in the reduction of the time interval between the interruption of the main current through the cell and the measurement of the single potential of the experimental electrode the original work this time interval was 0 02 second; it has been reduced to 0.002 second (Glasstone), 0 0001 second (Sand), and finally the cathode ray oscillograph reduces it to 0.000001 second The results are all explainable on the hydride theory of over-Transfer resistance is in itself a complex voltage quantity, due chiefly to the resistance of a film of gas covering the electrode surface, but partly also to the presence of a partially exhausted layer of electrolyte surrounding the electrode —K. H. Barnard: Some South African Crustacea. Three species of Crustacea are known to be injurious to pier-timbers immersed in the sea in South Africa. Two are cosmopolitan: Lumnoria lignorum (the Gribble) and Chelura terebrans. These are not more than a quarter of an inch in length. The third species is Sphæroma walkeri, which is common in India and seems to be spreading down the east coast in to Natal. It reaches half an inch in length and is capable of rolling itself into a ball.

#### COPENHAGEN.

Royal Danish Academy of Sciences and Letters, Mar. 25.—Martin Knudsen: The hot wire manometer. A rational construction is given, and a series of measurements have shown that this method, for a certain interval of pressures, gives greater relative exactitude than any other method.

April 8.—C. Juel: Von Staudt's definition. After reviewing the different forms in which this definition for imaginary elements has been given, the definition for projectivity is considered, and imaginary elements

are also discussed.

April 22.—Th. Mortensen: The postlarval development of some cidarids. The study of a series of young stages of Eucidans metulana proves that the interradial plates on the peristome of cidarids are not homologous with the interambulacral plates of the test. The periproct is never covered by a single large anal plate. The embryonal spines do not develop into the adult type of spines, but are dropped in the course of growth of the animal. The young Goniocidaris umbraculum is unique in having a bundle of spines, instead of a single spine, attached to each tubercle.

May 6.-Martin Knudsen: The thermal molecular pressure. The condition of equilibrium in a gas enclosed in a circular cylindrical tube the ends of which are kept at different temperatures, will ordinarily be that the pressure in the gas has the same value at both ends At low pressures deviations

from this law arise, and at very low pressures the law becomes completely altered. The author has investigated this phenomenon by a series of measurements and given a formula valid for all pressures.—
J Lindhard. The respiratory quotient during shortperiod muscular exercise. It has been maintained
that the real respiratory quotient during shortperiod muscular exercise is 1, that is to say, the work is performed on the expenditure of carbohydrates exclusively. Experiments now in hand show that this contention is untenable.—J. Hjelmslev. Invariant theory of power series. An independent and complete invariant system for power series of any number is stated as a convergence problem. The corresponding invariant theory comprises and simplifies the well-known theory of the differential invariant. It has also wider applications where the usual conditions for constancy or differentiation are not valid.

#### GENEVA.

Physics and Natural History Society, May 19 .-M. Gysin. On the chemical and mineralogical constitution of the limestones of Saint Best (Pyrenees). A chemical and petrographical examination confirms the hypothesis of MM. Bertrand and Longehambon on the metamorphic origin of these rocks of Urgoaptian age. The clay limestones have recrystallised with formation of silicates. The other minerals are due to fumerolles arising from the neighbouring grantes.—E. Briner and A. Schidlof. The boilingpoint paradox. As the result of their previous studies the authors arrive at the conclusion that it is the osmotic work of dilution of the vapour which provides the compensating work.—B. P. G. Hochreutiner: A new Australian species from Java. The author has collected in Java, at heights exceeding 2000 metres, a Cynoglossum which he connects with Cynoglossum australe, indicated by Bentham in the south of Australia, the province of Victoria, New South Wales, and Tasmania.

#### ROME.

Pontifical Academy of Sciences, April 24.—Wirtinger: Modern mathematics.—Hagen: Symmetry in the theory of surfaces. A problem, as yet unsolved, on a singular symmetry in the so-called Weingarten's identity.—Serini: Elastic co-actions. Various considerations of great importance to the technics of constructions are propounded.—Caronia: Di Cristina's new views on the processes of the defence of the organism against infections. According to these views, the infective process requires sensitiveness of the organism to the infective agent. Cure is associated with a process of de-sensitisation, which may be brought about artificially by special methods.— Teofilato: Investigations on the most suitable longitudinal profile of an aerodynamic tube.—Giorgi: Note on wave-filters.—Ernesta Porcu-Tortrini: Calculation of the powers of motors of the second order by reduction to the canonical form.—Neviani: Cheilo-porina circumcineta. The history of this species, discovered by the author, is summarised and co-ordinated with observations of other investigators.—Bresadola: (1) Selecta mycologica; (2) Basidiomycetes Philippinenses.

#### SYDNEY.

Linnean Society of New South Wales, April 27.—A. S. Hitchcock: Two new species of Setaria from Western Australia.—R. Greig-Smith: The influence of certain colloids upon fermentation. (Part iv.) Agar fibre in the alcoholic fermentation. Agar fibre, when in sufficient amount, accelerates the fermentation of invert sugar and thus falls into line with the

mineral colloids. (Part v ) Old or heated yeast cells are not stimulated by fullers earth (Part vi.) The non-adsorption of the invertase of heated yeast by fuller's earth. Heating the yeast to near the lethal point does not inhibit the production of an inverting substance, but this is indifferent to the presence of fuller's earth. Normal yeast under the same conditions secretes invertase, which is partly adsorbed by the mineral colloid—I. M Mackerras. Notes on Australian mosquitoes (Diptera, Culicidæ). (Part 1.) The Anophelmi of the mainland. New locality records and life histories are given, and the hitherto unknown male of A. atratipe Skuse is described.—Miss Lesley D. Hall · The physiographic and climatic factors controlling the flooding of the Hawkesbury River at Windsor. Two causes of recent decreases in height and frequency of floods suggested are (1) the building of dams on the Upper Nepean, and (2) a natural diminution in precipitation.

### Science for Citizenship.

PACILE criticism will always find vulnerable points of attack in any educational system. Only a short time ago, much was heard in the popular press of the views of prominent business men on the deficiencies of their office boys. Our educational system was therefore condemned in toto; our vast expenditure on education was adjudged complete waste. While such hasty judgments, based only on partial observation and imperfect evidence, may be set aside as carrying little weight, those who come most closely into contact with the products of the elementary school may still feel that all is not entirely well with education in England to-day. It may be granted that as compared with twenty-five years ago, when the Education Act of 1902 came into force, vast strides have been made. A higher standard is attained, a greater degree of accuracy and a stronger grip of the facts is to be observed, together with less tendency to a parrot-like repetition of the form in which the subject matter has been received. On the other hand, knowledge and inference which depend on that elusive quality, the intellectual flexibility and adaptability which for lack of a better term examiners connote by 'general intelligence,' seem rarely to show an advance commensurate with the improvement in specific branches of learning.

It may perhaps seem at first sight unfair that any educational system should be judged by the product of its lower grades—a product, too, of which the raw material is drawn in a large number of cases from sources which in all their conditions—intellectual, social, and moral—are unfavourable and sometimes entirely inimical to the aims and influence of the school. But it must be remembered that, since the beginning of the present century, what is almost a social revolution—still, however,

encountered while in the formative stage of their

It is not necessarily a mark of carping criticism to hold-indeed it would be idle to deny-that the qualifications of the elementary branch of the profession are still open to improvement in certain directions. but a great step forward has been taken towards the ideal of those who long ago hoped that the majority of teachers in the elementary school would one day hold a degree, not as a cachet in an already honoured profession, but as the outward sign of certain qualities and cultural attainment. What they looked toward in their staff of the future was not a band of specialists, each highly trained in his own subject, but of men and women of wide culture who might introduce into the elementary school a wider outlook and cultivate in the material on which they had to work an intelligence trained to alertness in appreciating the varied aspects of life and knowledge as a function of existence as members of an economic, social, and political community. To this end the secondary school and university courses then seemed the obvious avenue of approach. .

It must, however, be admitted that the trend of events has by no means justified expectation. It is not intended here to enter into a detailed criticism of the system of training teachers, but

the examination of students in training colleges, however logical its decision may be, and eventhough it may continue to inspect and take part in the examination of the technical side of training, the divorce between the examining body and the elementary schools will be complete, while, having in view the character of university courses as they are regulated at present, it may aggravate a tendency towards specialisation which is part a symptom, part a cause of the defects of our educational system as a whole

For many years the training college stood to the elementary school in a relation analogous to that of the university and the public school. For long it was for the brilliant boy or girl in the elementary school practically the only avenue of intellectual advancement Theoretically, it is true, it led to one profession only, but in practice some made it only a means to an end, taking advantage of the general rather than the professional education, and after a few years left the profession to attain eminence in other walks in life The academic side of the training college, from being subservient to the technical as it was when training was first instituted, became more and more important, and with the introduction and extension of university work it has tended, and tends increasingly, to overshadow the function of a training college as an institution of which the aim was not primarily academic. It must in fairness be recognised that this has been forced on the training colleges by the educational antecedents of the students, and no I magate that the academic education

d opportunity who passes

would thus be alleviated. Circumstances, however, have decreed otherwise, and instead of the numbers being fairly well balanced, science has as a general rule become preponderant. While the Board of Education has continued to examine the greater proportion of the students this has been of less moment. Those who were responsible for the general lines of the examination were well acquainted with conditions in the schools. Inspection by the Board of both colleges and schools secured that training should be carried on with a view to the need of schools for certain qualities and capacities in their teachers. When in the near future the Board will no longer be responsible for

laid down  $\omega$ . utes the most suitable  $\mu$ .  $\nu$  of an elementary school teacher.

It may perhaps appear that in ering the case of the teacher too great stress speen laid upon what is relatively a small portion of those who come under a part only of the whole system. But the teacher is a crucial example; in his case the effect is cumulative, and with present changes the tendency of which he is characteristic is increasing. Turn to the secondary school, and the same trend towards highly specialised courses in science is perceptible. In the Report of the

Board of Education for 1926, in dealing with the 'xamination of grant-aided secondary schools, it s stated that while Latin holds its own and Greek shows a decrease, the number of candidates taking chemistry and physics is increasing Of the number of candidates taking the First Examination in 1926, 40.2 per cent offered chemistry and 24.7 per cent. physics. In elementary and experimental science the figure was 5.7 only, and in general science 25 In the same way, of the 437 advanced courses recognised in 309 schools, 210 were in science and mathematics, 179 in modern subjects, and 37 in classics It must not be supposed, of course, that we regard the growth of science teaching in comparison with other subjects as unsatisfactory, what we object to is the virtual limitation of science in secondary schools to chemistry and physics, or to botany in girls' schools. Science, up to the standard of the First School Examination, should be of a more cultural, and less specialised, scope: it should be science for all, and not science as preliminary training for a university course.

In training colleges where students are working towards a degree, and in secondary schools, courses are framed with a view to the requirements of a university. Indeed, in some secondary schools the work is of a sufficiently advanced character to justify representations to the university that many students under existing regulations do no more than mark time in their first year of residence. Such an organisation of courses is justifiable only in so far as the aim of the university, the training college, and the secondary school is entirely identical. The university in its science courses aims at turning out men, especially those who seek honours, who have attained a more or less high degree of specialisation. But the aim of the secondary school in framing its courses, save for the exceptionally gifted intellectually or the favoured few whose means allow, should be to turn out pupils who are fitted to take their place as citizens intellectually equipped for the average life of the community. Still more does this apply to the elementary school. A fortiori, the teachers should be fitted by their own training to educate their pupils to that end. It is by no means clear that such highly specialised courses as chemistry and physics, still less perhaps biology or physiology, framed with a view to the requirements of a still more highly specialised university course, are the best media through which school and training institution can best perform their function. With

teachers themselves trained in highly specialised courses, we are in danger of a circle as narrow in its way as that of the older type of training.

Of the importance of science in any modern system of education there can here be no question: but there is danger of a certain confusion of thought. The value of the practical application of science was fully brought out during the War, it has been apparent in many of the problems which have arisen since the War, while scientific men have repeatedly and justifiably urged upon the public and the Government the fundamental importance of the promotion of scientific research for all departments of the administration and life of the community and the British Empire. This insistence upon the value of science, aided by a confusion between instruction in science and a technical training, has obscured its true function as an element in the training of the average individual in preparation for his duties as a member of the community. Now that science enters so widely and so intimately into every department of life, especially in all questions relating to health and well-being, it is essential that both the individual who ultimately through the vote will control policy, as well as those by whom that policy will be framed and carried out, should have a general knowledge of the scope and aims of science, as well as of scientific method and the mode in which science envisages and attacks its problems. It is, however, beyond question that it should be a general knowledge on broad lines: a specialised training in some highly technical branch of science is neither needed, nor indeed is ıt desirable The educationist need feel no alarm.

As a medium of culture, the history of scientific discovery opens up to the imagination vistas of man's endeavour which place it in the front rank of humanistic studies Through a general familiarity with the methods of scientific observation and experiment in the various branches of research, may be developed a critical attitude in judgment, a power of observation, and a capacity for orderly arrangement; while a knowledge of the questions with which science as a whole is concerned in the past, present, and the future, fosters the broad outlook which, in combination with these qualities, is essential in successful dealing with the problems of life. We doubt, however, whether much of the science teaching in schools, either primary or secondary, could be regarded as science for citizenship instead of science for specialists: and we should welcome a movement which would broaden its scope and change its character.

A Commence of the Commence of

# Musical Stimulus and Response.

The Influence of Music on Behavior. By Prof. Charles M. Diserens. Pp. v+224. (Princeton: Princeton University Press; London: Oxford University Press, 1926.) 11s. 6d. net.

THIS book covers so wide a field that a review of it is far from easy. From the title-page we learn that it was "presented as part of the requirements for the degree of Doctor of Philosophy in the Department of Psychology of the University of Cincinnati." The last chapter perhaps provides the key to the book's construction; it consists of a report of the writer's own experiments on the subject carried out during the year 1921-22 in that University. In the conduct of this research the author must have found it necessary to acquaint himself with the accounts of previously published work; the penultimate chapter, entitled "The History of Experimental Work on Reactions to Musical Stimuli," embodies the results of his extensive reading. Having proceeded thus far, he began to collect the published material concerning the influence of music on work and on the sick, the use of music in magic and in myth, and the reactions of animals to music. These (in reverse order), together with a lengthy introduction, are the titles of the remaining six chapters of the volume.

The core of the book—the record of the author's own experiments on the physiological effects of music—is as unsatisfactory as might be anticipated from a young tyro's attempt to deal with so extremely difficult a subject. One might have felt tempted to regard these early efforts as prolegomena to more mature research to be expected from him in the future. But Dr. Diserens is now (so we learn from the title-page) assistant professor of psychology in his old University; and, more Americano, it seems only too likely that he will be fully occupied henceforth in giving lecture courses, taking practical classes, and supervising crude research work, similar to his own, conducted by future aspirants for the doctorate in philosophy.

Yet Dr. Diserens has done good service in publishing the results of his wide reading. It may be objected that the data on which he draws are of very different value—good, bad, and indifferent—and that they might well have been supplemented with more adequate criticism than is here given them. On the other hand, there is not in existence any book containing so extensive a bibliography as this on the subject. The author, therefore, deserves our gratitude alike for his attractive literary style, and for having collated the results

of previous workers, many of them from somewhat inaccessible sources, which had not previously beer brought together in one volume.

When we read Dr. Diserens' review of the long line of experiments which have been attempted to determine the influence of music on such animals as the cobra, rattlesnake, lizard, pigeon, quail, pelican, mouse, rat, hare, squirrel, antelope. elephant, lion, tiger, coyote, monkey-not to mention many others—we are struck with the lack of previous training among the investigators in the methods of experimental psychology. The experiments might have been devised by the 'man in the street,' without any attempt to distinguish between the effects of music and those, say, of strangeness of the sound, wonder as to its source, curiosity in the movements of the performer, etc. But even if these precautions had been taken, it is doubtful whether a more satisfactory result than that reached would have been attained, namely, that animals vary widely in their response, according to their species and according to the kind of music to which they are subjected.

Substitute 'individual' for 'species,' and this is precisely the result of the many, often equally uncritical, experiments that have been performed on man. All that can be said in the case both of animals and of man is that music may act as a sedative, or as an excitant, or as a stimulant to uncongenial work. Dr. Discrens shows how in primitive magic music usefully serves to enhance bodily energy and to give the magician a feeling of increased power. He brings forward evidence which indicates the semi-magical nature of many work-songs in primitive people. He also rightly \* distinguishes in such music the different functions of rhythm, melody, and words, the first eliminating, he believes, "the strain of voluntary attention," and encouraging synchronous regular movements. the second releasing reserves of energy, and the third giving relief by reference to the desires and conflicts of the worker.

"At present," Dr. Diserens concludes, "we only know that music does influence the reactions belonging to work, but we cannot as yet control such effects with such certainty as to warrant general industrial use." But here, again, the fexperiments which can be adduced have not been carried out under sufficiently stringent conditions. The data quoted in regard to the results of sorting the mail to music at the Minneapolis Post Office are not in themselves adequate to convince the trained psychologist that, as Dr. Diserens maintains, they show "that music will cause ordinary

No. 3015, Vol. 1201

mail sorters to do more work and make fewer errors than usual." The influence of foreknowledge, suggestion by the investigator, and many other sources of error need to be eliminated in order to produce conviction. Nor is the author's acquaintance with modern statistical methods assuring when he concludes, from the data published by him on the effects of bicycle-racing with and without the accompaniment of music, that "the results seem to indicate a distinct stimulation of the athlete by musical stimuli."

The truth is that music exerts so many different responses—by its direct physiological effects, its arousal of imagery and association, its acceptance as purely musical meaning, as having a personified character, etc.—that different kinds of music cannot fail to produce different effects in different individuals, and that the same music may produce different effects at different times in the same individual.

This brings us to the problem—what  $\imath s$  music  $\imath$ Dr. Diserens maintains that intervals and chords do not present "genuinely musical situations," and that children and savages "delight in sound or colour combinations which pain the cultivated ear." Both these statements may be questioned, so far as the æsthetic attitude—regard for beauty—is Among the phonographic records emconcerned ployed by the author in his own experiments occur "Rosy Cheeks Fox Trot," "Dixey Medley" (banjo solo), and "Infanta March" (banjo). We wonder whether even the very highest powers of adaptation (the lack of which caused the works of Beethoven and Mozart, as well as Wagner and more modern innovators, to be characterised as unmusical when first they appeared) would enable "the cultivated ear" to designate these as æsthetically musical!

We may illustrate this difficulty by reference to the author's own experiments on the influence of music on the rate of respiration. He concludes that music, whether fast or slow, "accelerates respiration." But when we find that of the four records of 'fast' music which he uses, two—both banjo records—were disliked by three of the eight subjects and were by other subjects termed distracting, we may well ask, How, then, can we be sure that the influence of such records on respiratory rate is due to their musical character?

The whole subject—the effect of music on behaviour—needs to be attacked in a more thoroughgoing, systematic way. Yet, for the reasons already given, the psychologist is grateful to Dr. Diserens for his book.

# The Structure of Metals.

Metallographic Researches. Based on a Course of Lectures delivered in the United States in 1925. By Prof. Carl Benedicks Pp. x1+307. (New York. McGraw-Hill Book Co, Inc, London. McGraw-Hill Publishing Co, Ltd., 1926) 20s. net.

THE practice which has been developed of late years in the United States of inducing a European metallurgist of standing to give courses of lectures on his own researches at various centres is certainly an excellent one. Not only does it bring American metallurgists and students of the subject into personal touch with men who would otherwise remain nothing but names to them, but it also brings the trans-Atlantic visitor into touch with American affairs and institutions and sometimes engenders a higher degree of respect for them than had previously been entertained. Most of the lecturers thus brought to America have been British, but recently Dr. Carl Benedicks of Sweden and the German metallurgist, Dr. Guertler, have been included in the list. In the case of Dr. Benedicks, the subject matter of the lectures given has been put into book form under the title at the head of this notice.

Dr. Benedicks is of course a metallurgist and physicist of high standing, and the subject matter of his lectures accordingly attains a high level, although that level varies considerably between the different lectures reproduced in this book. Some of these-such as that dealing with the improvement of high-power photo-micrography of metals by means of the 'epiphragm'—have already been published in Great Britain, and so has much of his work on the 'homogeneous thermo-electric effect.' Another of his chapters is purely historical, and while we may understand his desire to secure recognition for a hitherto obscure Swedish metallurgist as the first observer of the Ac points in steel, this is not a matter of very wide interest. More directly important is the account of an attempt to determine the specific gravity of molten iron, an attempt which has met with a degree of success which is highly creditable when the extreme difficulties surrounding such experiments are con-

Of much more general interest are the two chapters dealing respectively with a kinetic theory of the constitution of solid matter and with the hardening of steel and other alloys. In the first of these Dr. Benedicks puts forward a kinetic theory of the space-lattice which is of essentially

physical rather than purely metallurgical interest. Indeed, it appears to have been evolved in part at least in order to account for the thermo-electric effects which the author claims to have established. It does not seem, however, that Dr. Benedicks' views really take us much forward. He objects to the suggestion that in addition to an attractive force-field surrounding an atom there should also be a repulsive field. He suggests that no repulsive field is needed to account for the properties of gases and liquids on a kinetic theory, and that its introduction in the case of solids is equally unnecessary According to this view, the atoms have no equilibrium position on a space-lattice, but merely a mean position which results from continual mutual collisions. That collision and rebound imply repulsive forces is, of course, obvious, but the suggestion is that these repulsive forces come into action only on actual contact. What, however, is really meant by 'contact' in the case of such a system as an atom is believed to be? Presumably, repulsion results from some sort of deformation produced in the atoms by their mutual forces, but it is difficult to believe that such deformation only becomes sensible at the instant when the outer electron orbits overlap or touch.

Perhaps the most interesting deduction drawn by Dr. Benedicks from his kinetic theory is that of the 'phoretic electron' mechanism of electric conduction. According to this view, electrons pass freely from atom to atom only when the outer electron orbits are in contact, and since the amplitude of atomic vibrations increases with rising temperature, there is a decrease of conductivity with rise of temperature. One difficulty of this theory, however, is that there does not appear to be any reason why this effect should not be of the same order in alloys as in pure metals, so that the low temperature coefficient of resistivity of solid solution alloys is not explained. Dr. Benedicks also attempts to explain super-conductivity at very low temperatures by the suggestion that at those temperatures the atoms become 'agglomerated,' i.e. remain in continuous contact, and therefore electrons can pass from atom to atom without resistance. This would be an excellent explanation if all metals and alloys became super-conducting when at temperatures near the absolute zero, but in fact the phenomenon is confined to a few metals only.

These somewhat important examples of the failure of Dr. Benedicks' theory suggest that it requires much further consideration before it can be seriously put forward, and it seems rather a

pity that it should have been made the subject of an educative lecture in America—at least in its present form.

Criticisms of a similarly serious nature can be brought against Dr. Benedicks' treatment of the theory of hardening of steel and other alloys. The view of the nature of hardening by the breakdown of a super-saturated solid solution and the resulting formation of finely dispersed particles of a 'precipitate' in the solid matrix is dismissed by the Swedish metallurgist on the ground of certain measurements of the electrical resistance changes in alloys during the course of hardening. It is a well-known fact that an element present in solid solution causes a far greater increase in electrical resistivity than the same substance present in the form of separate crystals. It is argued, therefore, that the breakdown of a solid solution by the formation of minute 'suspended' particles should be accompanied by a decrease in resistance. In fact, measurement shows that resistance increases up to the point where maximum hardness is attained and only then decreases.

The argument just cited, however, is based on a fallacious assumption, namely, that the resistivity of a substance A in which particles of B are suspended is independent of the dimensions of the particles. Actually, we have no experimental basis for that assumption, and there is, on the contrary, good reason to suppose that the presence of very minute suspended particles may produce a higher resistivity than the same material in atomic dispersion, in solid solution. According to the lattice distortion theory put forward by the writer some years ago, the high resistivity of a solid solution is due to the distortion of the lattice caused by the presence on it of the solute ator This also causes a certain moderate amour it hardening. But when such a composite lattice begins to break down, the first effect-which must in fact increase until all the solute at oms have begun to travel towards a state of separate aggregation—must be a partial breakdown of the parent lattice, and it is this further disturt ance of the parent lattice which will produce both mechanical and electrical hardening, i.e. increase of resistivity.

On this view, resistivity and hardness should attain their maximum at about the same stage and should then decline together, as experiment actually shows Now, what is Dr. Benedicks' alternative? He draws an interesting distinction between a 'super-cooled' and a 'super-saturated' sold solution, although it seems doubtful whether such a distinction has any real meaning. He

further suggests that, in a freshly quenched alloy or an austenitic steel, we have a super-cooled but not a super-saturated solid solution, and that agehardening in the alloys or the corresponding process in austenitic steel results from a transformation from the super-cooled to the super-saturated solution. Now it is well known that by rapid cooling and other means a super-saturated solution can be maintained without crystallisation, but it is quite another matter to suppose, as Dr. Benedicks does. that a super-saturated solution can be formed by transformation. The writer respectfully suggests that if a super-cooled solution, whether solid or liquid, is caused to undergo transformation, the result will never be the formation of a supersaturated solution, but a separation into two phases.

Somewhat similar criticism can be applied to Dr. Benedicks' remarks on hardening by cold work. This he ascribes to the production of multiple twinning, in spite of the facts that in copper and copper alloys the existence of twinned crystals confers no sign of hardness, while observation shows that twin lamellæ offer no obstacle to crystalline slip. Further, mechanical twinning is unknown in alpha-iron, yet that metal hardens vigorously under cold work. It would thus seem particularly unfortunate that Dr. Benedicks should have put before his American hearers a series of views so markedly at variance with those held by British and American metallurgists, while leaving his views open to such obvious and, in the writer's opinion, fatal objections. This is the more the pity, since Dr. Benedicks' contributions to metallurgy are so important that he should have had no difficulty in providing his audience with sound, well-established material, such as is to be found in his chapter on meteoric iron and invar, on a 'rational' section for ingots intended for coldworking, and on the 'hot wall' effect in corrosion.

W. ROSENHAIN.

# The Suppression of Mosquitoes.

Principles and Practice of Mosquito Control: being a Handbook to the British Mosquito Control Institute By John F. Marshall. Pp viii+39+20 plates. (Hayling Island, Hants.: British Mosquito Control Institute, 1927.) 2s. 6d.

ROM the British Mosquito Control Institute at Hayling Island, Hampshire, has been recently issued this handbook on the principles and practice of mosquito control, which includes also a brief account of the inception of the Institute and of the results of its work. The Institute owes

its existence to the success of an anti-mosquito campaign which was initiated at Hayling Island in 1920 to deal with the local mosquito nuisance which had become so intolerable that the inhabitants of the central residential district found it impossible to sit in their gardens in the late afternoons or in the evenings. Mr. F. W. Edwards, of the British Museum (Natural History), expressed the opinion that the trouble was probably due to the salt-marsh species Aedes (Ochlerotatus) caspius and A. (O.) detritus, and examination of some thousands of adult mosquitoes captured in the residential area during September and October proved that the latter species was almost entirely responsible. To Mr. John F. Marshall belongs the credit of beginning in 1920 investigations preliminary to the mauguration of methods of control. In April 1921, at a meeting of some seventy inhabitants, it was decided to institute a systematic campaign against the mosquitoes; committees were elected to deal with the various branches of the work, and a circular was issued to every householder on the island explaining the objects of the campaign and appealing for the assistance of voluntary workers and for financial support. A laboratory was improvised by Mr. Marshall, where mosquitoes could be examined and investigations on their breeding habits carried out.

Larvæ of Aedes detritus were found in 1921 in enormous numbers in certain accumulations of stagnating and partly salt water about a mile and a half from the centre of the residential district, and in the summer and autumn of that year several of these breeding places were permanently abolished, while a large number of others were treated with paraffin or with larvicides. During the next three years the work of abolishing or controlling the mosquito breeding areas was continued, and the nuisance progressively decreased and eventually disappeared. Evidence of this was furnished by a postcard 'canvass' of the residential district in October 1924, as well as by the fact that residents were able, for the first time in many years, to sleep out of doors. The inconvenience due to insufficient accommodation for the work in progress was severely felt, and Mr. Marshall generously erected at his own expense a separate building in which the various branches of the work could be adequately developed.

This building—the Institute—which was formally opened by Sir Ronald Ross in August 1925—contains eleven working rooms, and cost with its equipment about £4200. It is hoped that a scheme for establishing the organisation upon a permanent

basis may eventually be devised, and in preparation therefor the Institute has been incorporated. Up to the present the Institute has not received financial assistance from official bodies or local authorities—excepting a grant of £100 from the Ministry of Health in 1923 towards the cost of labour employed in certain experimental work—but has had to rely on voluntary contributions. An appeal is now issued for subscriptions—life members' and annual—and for donations to provide an annual income which will enable the work of the Institute to be carried on efficiently.

The success of the work on Hayling Island directs attention to the desirability of suppressing mosquitoes which, when present in numbers, cause general annovance by their bites, which are frequently followed by the development of sores and sometimes by even more serious consequences. These effects may be produced by Culicine as well as by Anopheline mosquitoes. This aspect of mosquito control is emphasised by the recent decision in the 'Paisley Case' (see NATURE, June 25, p. 934), the first of its kind under the Public Health Acts in Great Britain, in which the sheriff found that certain ditches had become so encumbered with silt and vegetation as to be ineffective as water courses and that the ditches and the adjacent overflowed ground had become a breeding place for large numbers of mosquitoes, and he ordained that the owners should clear the ditches and maintain them clear.

Communities which may decide or be compelled to undertake mosquito control would do well to consult this handbook for the sequence and nature of the operations and to base their methods, as at the Hayling Institute, on a true scientific foundation. For example, there are twenty-five species of mosquitoes in Britain which differ considerably in their habits, and in the period of hatching out, so that it is necessary to discover first the species which are prevalent in the district, to estimate which is the most important and should therefore be first attacked, and to see that waste of effort is avoided, for example, by treating with larvicide only the water in which larvæ have been actually observed. Useful suggestions are given for inspecting possible breeding places, for applying larvicides, for 'unstagnating' the water, and for recording progress in a central institute.

There will always be, as is pointed out in the handbook, a certain section of the public who will refuse to assist in the work of mosquito control, maintaining that the task is hopeless. This attitude of mind should be dealt with, as in the

first year or two at Hayling Island, by the education of public opinion by means of demonstrations of living and preserved specimens of the local mosquitoes and of diagrams illustrating the progress of the campaign.

The handbook is illustrated by excellent photographs prepared by Mr. Marshall, and by useful diagrams which help the reader to recognise the more important larvæ and adults. But its principal value is as a record of the means by which the serious nuisance due to mosquitoes was overcome within four years in a somewhat difficult terrain—a noteworthy achievement on which the director and his collaborators are to be warmly congratulated.

# Climatic Changes: their Causes and Influences.

(1) The Pulse of Progress · including a Sketch of Jewish History. By Ellsworth Huntington. With a Chapter on Climatic Changes, by G. C. Simpson. Pp. x+341. (New York and London: Charles Scribner's Sons, 1926.) 21s. net.

(2) Climate through the Ages: a Study of the Climatic Factors and their Variations. By
C. E. P. Brooks. Pp. 439. (London: Ernest Benn, Ltd., 1926.) 15s. net.

(1) R. ELLSWORTH HUNTINGTON, of the Geographical Department of Yale University, in a series of thirteen interesting volumes, besides numerous papers, has ingeniously and eloquently advocated the view that in the environment of which man is the creature, climate is the most powerful factor As a corollary to this view he holds that climatic changes are the main cause of the rise and fall and of the migrations of In the present work he puts his civilisation. theory in a more attractive form as he limits the climatic pulse in historic times to a comparatively narrow beat, as he explains the vicissitudes ofancient Greece by climatic influences of the order of a change of mean temperature of the year from 62° F. to 63·1° F., with a variation of humidity of 10 per cent. To determine the mean annual temperature within 1·1° F. is practicable for few countries only; and it would be impossible to prove or disprove so slight a change for any country except within recent times. That climate is an important factor in human welfare, and that people's working efficiency varies with weather, is universally recognised; and these facts are confirmed by the interesting statistics brought forward by Mr. Huntington from American industrial and

educational records. It may nevertheless be doubted whether the climatic changes in historic times have been the main factor in the migration of races and civilisations.

Mr. Ellsworth Huntington's books are always interesting, for he is graphic and collects striking examples from a wide range of evidence. His information is obviously of very unequal value, but he consoles himself with the reflection, "Perhaps your answer is wrong, never mind." Perhaps on that principle he retains the generally rejected explanation by Dr. W. H. S. Jones that the decay of Greece and Rome was due to an increase of malaria owing to a decrease in rainfall.

The new ground covered in the "Pulse of Progress" is the application of Mr. Huntington's principles to the natural history of the Jews. He has restudied the Bible and its newer criticism, and has re-written the Bible story in accordance with the geographical control of physical agents. His version is like that of the "Darkie Sunday-school":

"Bring yer sticks o' chewey gum and sit upon de floor

And I'll tell yer Bible stories dat yer never heard before."

His account of Jewish history is not likely to be reprinted in Great Britain by the Sunday School Union, but is in accordance with the general trend of advanced Biblical criticism. He points out, for example, that the plagues were the natural result of a succession of low Niles. His account, however, shows that the climate of Palestine and Egypt has been practically unchanged throughout historic times, except for the minor fluctuations that are inevitable owing to the complexity of the factors that control weather. The volume includes an interesting chapter on what Mr. Huntington describes as the suicide of Russia by the expulsion of its aristocracy and the massacre of more than a million of the more intelligent citizens. Australia he describes, on the other hand, as having "evolved a social and political system which is pre-eminent as one of the important recent contributions to human progress."

One of Mr. Huntington's most striking contributions to climatic variations within historic times has been deduced from the variations in rate of growth of the big trees of California; their evidence is complex, as different trees did not vary in the same way simultaneously, and their records require a lot of interpretation to make them tell the same tale. Their restricted distribution, as pointed out by Dr. G. C. Simpson in a weighty article reprinted by Mr. Huntington, proves that there has been no

serious change in the climate of the belt occupied by these trees during the past 2800 years. Mr. Huntington has introduced one correction on the interpretation of the big tree records, based on evidence from the Caspian. This correction is rejected by Dr. C. E. P. Brooks in (2) "Climate through the Ages," although he supports Mr. Huntington's main thesis by accepting important changes of climate within the historic period. Dr. Brooks holds that major climatic changes are due to the interaction of many geographical causes and that former glaciations and warmer periods were the result of the different distribution of land and water; but as there has been no appreciable change therein during the past 2000 years, he assigns the climatic variations during historic times to solar activity. According to his view, climate is under solar control when land and water are stationary.

Dr. Brooks compares the evidence of the big trees with the variations of the nearest salt lakes. The country in which they occur must have had a wet climate during the glacial period, which was followed by a dry warm interval, before another cold wet episode. The evidence is not altogether harmonious, for the lakes indicate a maximum rainfall at 1000 B.C. (p. 393), which was followed by a dry period until A.D. 800; according to the big trees, the wettest time was between 480 and 250 B.C., and it was followed by drought until A.D. 850. Toward the end of this time the climate was so warm that, according to Dr. Brooks, there was no perennial ice in the Arctic Ocean in the seventh century and none at all in the Greenland seas. Since then, the Norse colonies have been frozen out by increasing cold. Dr. Brooks connects this change with the end of a warm dry period in Britain in the ninth century and the final deterioration of the British climate about A.D. 1000. That the climate of Greenland has become more severe in recent times is indicated by weighty evidence; but a change of this extent in the Arctic Ocean would surely have been accompanied by greater changes in the British climate, and it is contradicted by the evidence of the Sagas. The frequent assertion that the British weather has become milder instead of more severe during the past eighteen centuries is opposed to any fundamental change in the Arctic Ocean.

The effect of geographical changes in climate naturally leads to a discussion of the Wegener theory of continental drift, which has received most support from the meteorologists; and it is interesting to note that Dr. Brooks emphatically rejects it as unnecessary.

# Our Bookshelf.

Condensing Plant: a Complete Treatise on the Principles and Details of Construction of Modern Steam Condensing Apparatus; for Designers, Users, and Students. By R. J. Kaula and I. V. Robinson. (The Specialists' Series.) Pp. xiii + 400. (London: Sir Isaac Pitman and Sons, Ltd., 1926.) 30s. net.

A MODERN steam power plant can be divided into three main sections the boilers and their accessories, the turbines, and the condensing plant. Most text-books on steam machinery deal partially with the three sections, but the multiplication of types of machinery in power houses and the increasing complexity of the systems tend to make specialisation desirable. Many engineers therefore will welcome this book, which is devoted entirely to the condensers, air pumps, feed pumps, and feed systems. All the earliest steam engines were condensing engines, and the patent of Savery intro-duced the practice of surface condensation. Newcomen led the injection water into the steam cylinder, and Watt made the capital improvement of a separate condenser. Of other inventors, one of the least known is Samuel Hall, whose patent for surface condensers for steam vessels, taken out in 1836, is a most interesting one. With the introduction of high-pressure steam the jet condensers gave place to surface condensers, and with the coming of the steam turbine a new chapter in the history of the condenser opened. An immense amount of investigation has been carried out on the design of condensers, the corrosion of the tubes, new forms of air pumps, and improved systems of feeding the boilers, and all these matters are admirably treated by Messrs. Kaula and Robinson in the work under notice.

Industry and the State: a Conservative View. By Robert Boothby, John de V. Loder, Harold Macmillan, Hon. Oliver Stanley. Pp. viii + 269. (London: Macmillan and Co., Ltd., 1927.) 6s. net.

This book is an interesting expression of the views held by what may be termed the left wing of the British Conservative Party. Opposed on one hand to laissez-faire as on the other to socialism. it seeks a via media between these conflicting ex-The authors are convinced that an advance in the economic status of the wage-earning classes is the necessary corollary of their advance in political status, and they seek the means whereby the improvement may be effected. Their suggestions do not partake of novelty, but they are urged with some force and ardent conviction. the planning of economic policy they would have an Economic General Staff. Industrial Councils and Wage Boards would be created with increased powers; and co-partnership would be made an essential part of industrial organisation. The writers have read widely, and there is throughout an air of attractive goodwill about their proposals. How far they are likely to attract attention is another matter. Much, for example, of the recent legislation they quote in support of their views is open to a different interpretation from what they place upon it Their account of the characteristics of industrial ownership follows that of an American, Mr. Robert Brookings; but if they had considered the arguments of Prof Henry Clay, they would have seen that most of the inferences they draw are quite misleading. Their insistence that there is an incompatibility between socialism and private property is contradicted by the work of Mr. and Mrs Webb and Mr. R H Tawney; they do not seem to grasp the distinction made by most socialists of authority between property as use and property as control. But their book is doubtless meant to be no more than a tentative sketch: and as such it is an interesting expression of a significant tendency which is not unlikely to

Engineering Metallurgy: a Textbook for Users of Metals. By Prof. Bradley Stoughton and Prof. Allison Butts. (Metallurgical Texts.) Pp. xi +441. (New York: McGraw-Hill Book Co, Inc.; London: McGraw-Hill Publishing Co, Ltd, 1926.) 20s. net.

As the range of steels and non-ferrous alloys is extended it becomes more and more necessary for the engineer to have some metallurgical knowledge, at least sufficient to enable him to make use of metallurgical literature It is becoming common to include some training in metallurgy in the university and technical college courses for engineering students, and the need for suitable text-books has arisen. The manual compiled with this object by Profs Stoughton and Butts is not quite successful in approaching the subject from the point of view of the engineer, which is distinctly different from that of the student of metallurgy. It is rather a condensed text-book of metallurgy, in which each section is treated in brief outline. without undue detail. Short sections on fuel questions, on heat losses, and on pyrometry are included, and the reader can obtain from it a general survey of metallurgical practice, from the treatment of ores to that of castings and forgings.

It is on the physical and metallographic side that the book is weakest, and there are inaccuracies on certain points, whilst the discussion of a subject of such importance to the engineer as the heat treatment of steel is very sketchy. Surely, also, since photo-micrographs are freely introduced, some short account should have been given of the use of the microscope in the engineering works. It is quite possible to make the young engineer familiar with the processes of preparing sections for microand macro-examination, and with the general characteristics of such materials as he may have occasion to use, although years of experience-may be needed before he can interpret unusual appearances in a critical manner. The authors have had to bear in mind the curriculum in American colleges, and this has no doubt restricted them in their treatment, but a different method of approach is needed in an engineering course on scientific principles.

Handbook for Prospectors. By M. W. von Bernewitz. Pp. ix + 319. (New York: McGraw-Hill Book Co., Inc.; London: McGraw-Hill Publishing Co., Ltd., 1926) 15s. net.

It may be very gravely doubted whether it is possible to write a handbook for prospectors which is of any use to the men for whom it is intended. Modern prospecting expeditions, equipped and sent out by important syndicates, are usually under the charge of trained mining geologists, who require no information upon elementary crystallography or geology. On the other hand, the rough practical prospector, who has in the past been responsible for the discovery of many of the world's most important mineral deposits, neither knows nor cares, nor wants to know anything about the "dodecahedron of the isometric system" phraseology is of quite another type. It is difficult to imagine what kind of a prospector would be benefited in the slightest degree by such drawings as the author's Fig 28, which shows a hand drill and hammer; it surely ought to be obvious that a man who does not know what these are had better leave prospecting alone; incidentally, it is probably impossible to imagine a hammer shaft worse shaped than that shown in the figure in question; it is quite certain that no practical prospector would ever attempt to use such an obviously futile appliance. Again, the detailed instructions given for such things as tying packs and arranging and priming a dynamite cartridge are surely unnecessary and can never be learnt from books. It would also be interesting to know how many prospectors the author thinks would be benefited by his table of the atomic weights of the elements as determined by the International Committee. There may be one or two things in the book, particularly in the first twenty-three pages, which may be of use to the prospector; the remainder would probably be useless to him even if he could understand it.

Monograph of the Sea-Snakes (Hydrophiidæ). By Malcolm Smith. Pp. xviii + 130 + 2 plates. (London: British Museum (Natural History), 1926) 10s.

This work in its scope and arrangement follows the lines of the British Museum Catalogues; the greater part of the text is purely systematic in nature, but the author's views on the relationships of the group and some notes on habits are included in the introduction. The list of references under each specific heading is not supposed to be exhaustive, but an attempt has been made to include all those of any importance from which the student may obtain any additional information he may require. The book will be welcomed by all systematic herpetologists as the first complete account of the Sea-snakes since the publication of Boulenger's "Catalogue of Snakes" (1896); based on the largest collection of these animals that has yet been brought together, the author's views carry weight and conviction. The most important proposed change is the recognition of two sub-families, the Laticaudinæ of Australian origin and the

Hydrophiinæ of Indo-Malayan seas; these two sub-families are established chiefly on osteological features of the skull and are regarded as two separate evolutionary lines. The author's conception of the genera agrees closely with that of Boulenger, but he finds that many of the species recognised by the latter are untenable; the names used are for the first time brought into line with the International Rules of Zoological Nomenclature.

The Theory of Equations and the Complex Variable. By Prof. Rai Charan Biswas. Pp. viii +269. (Calcutta: Chuckervertty, Chatterjee and Co., Ltd, 1926.) 3.8 rupees.

This volume contains an introduction to the theory of algebraic equations as the subject was known to mathematicians of half a century ago. It gives the usual theory of cubic and biquadratic equations, Fourier's and Sturm's methods of separating the real roots, also chapters on symmetric functions of the roots, determinants, and elimination. The only methods of numerical solution considered are those of Newton, Lagrange (by continued fractions), and Horner. Great advances in this branch of the subject have been made in the last twenty years, so the book is distinctly out-of-date on the numerical side. Its only novel feature lies in the inclusion of the equations satisfied by the sum and difference of two roots of an equation.

The author gives an account of the geometrical representation of complex numbers, with some applications to the theory of equations. Cauchy's method of locating the complex roots of an equation is explained, but the book is in no sense an introduction to the theory of a complex variable. Many of the problems are interesting, and none of them involves much theoretical difficulty.

W. Ě. H. B.

The Mind and the Film: a Treatise on the Psychological Factors in the Film. By Gerard Fort Buckle. Pp. xiv + 119. (London: George Routledge and Sons, Ltd., 1926.) 5s. net.

In "The Mind and the Film" the advance in technique in kinematography is related to the way in which a 'story' should be presented so as to secure its full psychological effect. The 'story' itself, the mode of its expression, and its angle of conception and balance, are considered in the first part of this little book; while the second part is devoted to a brief but practical discussion of the uses of photographic 'aids to the mind.' Suggestive hints, linked up with more or less obvious physiological and psychological principles, are given to the producers of films throughout; and the ordinary reader who enjoys the 'pictures' will find not a little interest in reading of the devices by which his understanding is helped, and his emotions stirred, while he follows them. The book is written in non-technical language so far as psychology is concerned, but abounds in the somewhat uncouth vocabulary of the motion picture camera.

## The Constitution of Ordinary Lead.

After repeated failures I have at last succeeded in obtaining the mass-spectrum of ordinary lead. This has been done by the use of its tetramethyl compound, a pure specimen of which was kindly supplied me by Mr. C. S. Piggot, of the Geophysical Laboratory, Washington. The vapour was first used diluted with carbon dioxide but later was admitted pure into the discharge tube. It works smoothly, but very long exposures are required. The three principal lines are 206 (4), 207 (3), 208 (7). The figures in brackets indicate roughly the relative intensities and are in good agreement with the atomic weight 207.2. This group is beautifully confirmed by its repetition 15, 30, and 45 units higher, corresponding with the mono-, di-, and trimethyl molecules. Comparator measurements show that all three of these lines are integral with those of mercury to an accuracy of 1 or 2 parts in 10,000.

There are indications that many other isotopes may be present in small proportions. An exceedingly faint line at 209 occurs in the atomic group, and on one plate is visible on the PbCH<sub>3</sub> group. This is almost certainly an isotope. Search for lighter mass numbers in the atomic group is unfortunately impossible owing to the mercury group and its penumbra. It was hoped that definite information would be available from the PbCH<sub>3</sub> group, but the unexpected appearance of lines certainly due to HgCH<sub>3</sub> complicates this region too. The evidence suggests the possibility that 203, 204, and 205 are all present in small proportion, but certain proof will only be available when mercury can be eliminated from the discharge.

The mercury lines in these experiments were more intense than any previously obtained, and indicate with certainty the presence of a seventh isotope Hg<sup>196</sup>. Comparative exposures show that this is present to the minute extent of 0.04 per cent.

F. W. ASTON.

Cavendish Laboratory, Cambridge. July 30.

## Helium Compound.

It has been shown by Paneth and his co-workers in Berlin that any element which stands in the periodic table from one to four places before a noble gas will form an easily volatile hydride; such is the case with lead and bismuth, the hydrides being gaseous at ordinary temperatures. If, as is generally supposed, orthohelium has one electron relatively far removed from the nucleus with respect to the other, it is possible that in this state the helium atom might exhibit properties similar to, though less pronounced than, those of hydrogen; that is, it might be expected to combine with such an element as bismuth, and the resulting compound would in all probability be a gas.

The point can be investigated by the use of the radioactive isotopes of lead and bismuth, and a series of experiments has been made with this object in view. The results seem to indicate that such a gaseous compound does exist. Helium and other gases, at from 0.5 to 1 mm. pressure, were passed over a strong radioactive source of radium B and radium C.

then, through a U-tube partially filled with glass wool, into a bulb containing a zinc sulphide screen; the gases could be excited in the tube surrounding the source by means of an electrodeless discharge. The relative amounts of radioactive gas formed were estimated by the number of scintillations appearing on the screen.

When a gas was circulated over the source and through the bulb, with no discharge passing, only a negligible number of seintillations was observed. With excited hydrogen a very large number appeared; it is most unlikely that these could have been due to particles of the source carried over in suspension, because similar experiments with oxygen and nitrogen gave no effect. When helium was used a radioactive gas was also found to be carried over into the bulb; the number of scintillations observed was much smaller than with hydrogen, yet much greater than that to be accounted for by hydrogen impurities in the helium or by radium emanation which had been occluded in the source. It thus seems probable that gaseous helides analogous to Paneth's hydrides can be formed.

D. M. MORRISON.

The Cavendish Laboratory, Cambridge, July 14.

# Breeding Places of Sucking-Fish in the North Atlantic.

In a note in Nature of Dec. 4, 1926, p. 805, Dr H. C. Delsman described an attempt to hatch some fish eggs from the Java Sea which, according to his investigations, belong to Echeness naucrates L. Hitherto nothing at all has been known about the propagation of this sucking-fish which is so common in tropical seas. Nor have we been any better acquainted with the breeding places and development of other sucking-fish, in spite of the attention given to these fish since early times.

Through the cruises in the years 1911-1922 of the Dana and other Danish ships in the tropical and subtropical northern Atlantic, some material has been collected that will throw a light on the breeding places of a few species of Echeneididæ. In this material we find post-larval stages (from a length of 5.6 mm) of 3 species, namely, Echeneis lineata Menzies, Remora remora Linné, and Remora clypeata Gunther (probably = R. albescens Temm. and Schl.) In the thousands of towings not more than the following numbers have been taken: about twenty specimens of R. remora, about ten specimens of E. hneata, and only one of the last-mentioned species. All these post-larval stages have been taken in pelagic tow nets, working between the surface and a depth of 25-50 metres (one of them was taken at a greater depth, but may have been caught in hauling in the implement). All the post-larvæ were caught in the months April-November, and none of them during the months of the colder season (December-March).

The post-larvæ of *R. remora* have almost all been taken in the months of June-July, and one only in September and November (the most northern and the most southern find). The catchings of *E. lineata* extend over the months of June to November, with only a single find in April. The only specimen of *R. clypeata* was caught in November. So it appears—at least as to *R. remora*—that there is a sharply limited spawning time.

The free pelagic existence of the post-larvæ is evidently of a rather short duration for these species. At a length of 3-4 cm. R. remora joins its host, and

<sup>1</sup> In Comptes rendus de l'Acad des Sci., Paris, 1926, t 182, p. 1293, I have given a short survey of these young stages as to the position and development of the sucking disc during the ontogenesis.

scarcely any more are taken freely pelagic.<sup>2</sup> At any rate, E. lineata has obtained the full efficiency of its sucking disc when it has reached a length of 5 cm. (inclusive of the long caudal fin that makes about

three-tenths of its total length).

The distribution of the post-larvæ is given on the accompanying map (Fig. 1), from which it will be seen that the two species—particularly R. remora—have chiefly been taken in the Sargasso Sea—where most of the fishing was done; very few have been taken north of 30° north latitude, and none at all have been taken in the precincts round the Caribbean islands, where the fishing chiefly was carried out during the months of November-April. The above-mentioned

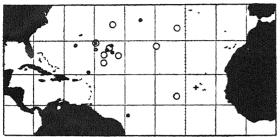

Fig. 1.—Distribution of post-larval stages of sucking-fish in the North Atlantic • Remora remora L , +, Remora clypeata Gthr , , , Echeneis lineata Menzies

species in this way appear to be typical oceanic spawning species. A very striking fact is the total absence of stages of the most common sucking-fish in the West Indies, E. naucrates L. I therefore draw the conclusion that this species, so numerous along the coasts, spawns near these in shallow water and most likely in the warmest season, at which time of the year little fishing has been undertaken by Danish ships in the West Indian seas. The correctness of this conclusion seems to be confirmed by Delsman's find in the Java Sea. In the Atlantic north of the equator we shall surely be able to find this species, particularly in the shallower parts of the Caribbean Sea in high summer.

As to the species inhabiting the Mediterranean, the spawning places, season, etc., is, so far as I know, still quite unknown.

Å. VEDEL TÄNING.

Carlsberg Laboratory, Copenhagen, June 10.

## Chromium-plating and Resistance to Corrosion.

The statement made by H. C. H. C. in Nature of July 2, p. 6, on the subject of the protection afforded by electro-deposited chromium, as mentioned in Mr. U. R. Evans's book, "The Corrosion of Metals," seems so definite that, in view of the contrary experience of several workers specialising in electro-deposition for the prevention of corrosion, it seems desirable to direct attention to the fact that, so far, preliminary tests have indicated that electro-deposited chromium cannot be looked upon as a reliable protection of iron and steel from corrosion.

Much depends on the thickness of the deposit: comparatively thin deposits have given disappointing results. Thus, a thickness of 0.0013 cm., which gives ample protection in the case of a zinc deposit and fair results with nickel, is not sufficient in the case of chromium, which rapidly breaks down in the salt-spray corrosion test; but, as I have already pointed

 $^2$  A survey of the smallest known adolescent stages of the different species has recently appeared by E. W. Gudger (Am. Mus. Novitates, Nov. 17, 1926).

out elsewhere, the hygroscopic corrosion product which is formed may have a marked influence in accelerating the corrosion. The salt spray corrosion test may, however, be taken as a particular simulation of marine conditions.

The behaviour of chromium as a corrosion preventive seems to vary, some specimens having been found to resist corrosion far better than others. The explanation is probably to be found in the inherent tendency of chromium to become passive, in which condition it presumably acts cathodically to the iron, actually accelerating the process of rusting.

Further, the statement that chromium does not adhere well when deposited directly on steel is not in accordance with the experience of most workers. On the contrary, it adheres much more readily to iron or steel than is the case when a coat of nickel is first deposited. Certainly, stripping troubles are much

more prone to occur in the latter case.

The deposition of chromium has a certain future before it on account both of its hardness and resistance to tarnish, and it is also being applied in certain special processes (for example, fine line engraving). But, so far, its use as a protection of ferrous metals from corrosion has not yet been definitely demonstrated; zinc and cadmium deposits are far superior to chromium in this respect.

S. Wernick.

Woolwich, S.E.18.

MR. WERNICK has performed a service in stating his experience on the degree of protection to be expected from electro-deposited chromium. Much of what he says is quite true, and indeed there is no disagreement between his experience and the guarded statements on this subject made by Mr. Evans in his book, and in my review of it to which he refers. Thus Mr. Evans states (page 208): "Chromium-plated articles which are now being manufactured in this country are said to withstand sea-water and tarnish"; and again, "The problem has been attended by many difficulties, some of which have not wholly been overcome as yet." In my own review I wrote, "It is stated that plated articles manufactured in this way withstand corrosion. . . ." Mr. Wernick seems to assume that Mr. Evans and I have expressed an opinion in favour of chromium more definite than is actually the case.

chromium more definite than is actually the case. It must, however, be emphasised that several workers who have tested chromium-plating have published the view that, if the plating is satisfactorily performed, it does give considerable resistance to corrosion. References to these are given in footnote No. 2, p. 208, of Mr. Evans's book. Some of them may not be entirely unprejudiced, but taken as a whole they cannot be neglected. No doubt the results, as Mr. Wernick says, are somewhat variable. This is true of any new process. In the July issue of Industrial and Engineering Chemistry, Killifer has published an article in which he definitely recommends chromium-plating as a means of combating cases of corrosion which are encountered in the chemical, oil, and paper industries. In the course of this he states that the unsatisfactory results obtained with early samples of chromium-plating were due to pin-holes.

With reference to the question of the direct deposition of chromium on steel, Ollard, who has done so much work on the question of the adhesion of many sorts of depositions, stated at the British Association in 1925 that "the best results were obtained if the steel was first coated with nickel or copper." If Mr. Wernick has obtained better adhesion by depositing chromium direct, he has achieved a considerable success, and it is to be hoped that he will publish his method in full, if he has not already done so.

So far as I have been able to ascertain, his statement

that "the salt-spray corrosion test may . as a particular simulation of marine conditions," does not command general acceptance. I have consulted Dr. Bengough, who has had wide experience of this test, and he informs me that it all depends on how it is carried out. It was introduced by the Bureau of Standards, and as carried out by them certainly did not simulate marine conditions, since the articles in question were exposed to salt spray kept permanently moist. If the test is modified so that the articles are alternately wetted with salt spray and dried at intervals, a nearer approximation to marine conditions is obtained. Salt spray, however, is not sea-water The latter contains a variety of salts and some colloidal substances. A still closer approximation is furnished by using sea-water spray with alternate wetting and drying. Even this, however, is not the same as marine conditions themselves. Dr. Bengough's view is that no artificial test of this kind which has yet been devised can really take the place of natural marine conditions.

Mr. Wernick's statement that chromium may act as a cathode against iron is very probably true. Certain chromium alloys do behave in this way. Chromium-plating is therefore comparable to nickelplating rather than to zinc-plating. The question is, is it better to plate with a cathodic material such as nickel or an anodic material such as zinc? The eathodic material will only protect if it is non-porous. Most electrolytic deposits are porous, but if they are hard the porosity can be greatly reduced by polishing. A view widely held by those with a practical experience of plating is that the protective qualities of nickel are largely connected with the fact that it can be well polished. Chromium deposits should have the same character. Anodic coverings such as zinc will protect iron even if porous, but only at the expense of the zinc. The protection will continue until the zinc is used up by the anodic corrosion. It is not difficult to understand why salt-spray tests give good results with zinc-covered articles, but it does not follow that these would have a long life in a marine atmosphere, because the rate of attack of zinc by sodium chloride solution in the presence of oxygen is very rapid, as is H. C. H. C. well known.

## A Relic of Sir Edward Frankland.

In "Sketches from the Life of Edward Frankland," printed in 1902 for private circulation (Spottiswoode and Co., 1902), and which for the greater part is his autobiography, reference is made to his apprenticeship days in Lancaster.

Frankland mentions a "delightful occupation devised to prevent my idle hands from finding some mischief still; . . . this was the making of mercurial

ointment.

"In a room on the first floor there was a very large marble or serpentine mortar, about 2 feet internal diameter. The pestle was about nine inches in diameter and one foot long, with a wooden shaft about six feet long securely fixed into it, its other end working loosely in an iron ring fixed to a beam in the ceiling. Thus the pestle could be worked round and round and backwards and forwards in the mortar.

"For the preparation of mercurial ointment, about fourteen pounds of hog's lard and five or six pounds of quicksilver were placed in this mortar and had to be triturated until a magnifying glass failed to show any globules of mercury. This blending of mercury with lard is an exceedingly tedious operation; working, in the aggregate, two full days a week, it required about three months to complete it. Moreover, the resistance to the motion of the pestle in the lard is

very great, making the labour very hard and the arms ache"

Owing to a rumour that a relic of Sir Edward Frankland might still exist in Lancaster, the writer called on the present owner of the premises at which Frankland served his apprenticeship (Mr. A. H. Robertson) and was shown the mortar and pestle situated exactly as described above, covered with

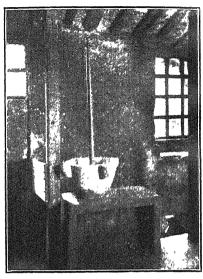

Fig. 1 —Room at Lancaster with pestle and mortar used by Sir Edward Frankland.

the dust of ages, in the semi-darkness of a small upper room where one could visualise the apprentice and his successors grinding in the true 'Mantalini' spirit of submission.

Mr. Robertson has generously presented the mortar and pestle to the Lancaster Museum, where it will shortly find a permanent home.

The accompanying photograph (Fig. 1) showing the old mortar and pestle *in situ* was taken by Mr. Wynespeare Heibert of Lancaster. W. F.

## Unusual Microstructure in Iron and Tungsten.

In the Metallurgist for June 24, 1927, page 88, F. S Tritton describes some unusual microstructures miron. One of these, originally described by Andrews in 1895, is found in pure re-melted electrolytic iron in the cast condition. The large crystals of which it is composed appear to be broken up by numerous sub-boundaries, but the etching tints indicate that these secondary grains have nearly a uniform orientation within the boundaries of the main crystal. Tritton has confirmed this by the appearance of the slip planes when the metal is strained.

Some years ago we observed a similar structure in tungsten which had been quickly cooled from the molten state. The appearance of an etched section (×200) is shown in Fig. 1 and is identical with the structure shown by Tritton. The difficulty of developing the sub-boundaries by etching is greater when the longer axis of the small grains, which have a columnar shape, is in the plane of the specimen, as in the case of iron. As the large crystals in our specimen are several millimetres in diameter, it has been possible to determine the orientation of the small grains within the boundaries of one crystal. A beam of X-rays was directed upon the polished

and etched surface of one of these crystals whilst the specimen was rocked through a small angle. diffraction pattern obtained is practically the same as that given by a true single crystal, but the spots are slightly more spread. This indicates that the small grains formed by the sub-boundaries have a

FIG 1.

nearly, but not quite, uniform orientation in each crystal.

We suggest that the sub-boundaries are formed under the influence of stresses set up during the rapid cooling of the metal. A somewhat similar break-up has been observed by us (Journal of the Institute of Metals, 107, 36; 1926) when tungsten rods are mechanically deformed by swaging

## Dug-out Canoe in Algoa Bay.

Mr. FitzSimons, in his letter published in Nature of May 21 (vol. 119, p. 746), gives an account of a derelict canoe that was washed ashore in Algoa Bay, South Africa, in February of this year. A study of the photograph which accompanies his letter indicates that he is mistaken in attributing the canoe to the 'Mawken' or, as they are usually known in this country, the Salons of the Mergui Archipelago. The Salon canoe has a 'step' in both bow- and stern-end, and there is no trace of anything of this kind in the canoe at Algoa Bay. On the other hand, the highcurved prow, broken off short at the base, and the flat but narrow stern-end clearly indicate that the canoe originally came from the Nicobar Islands. The side blocks shown in Mr. FitzSimons's photograph are for the attachment of the thwarts, made of split bamboo, and for the support for the outrigger. In some cases the canoes are fitted with one or more short masts, which are stepped on the thwarts, but in others they have a single mast fitted with a large square sail. The canoes are steered by a paddle.

The Nicobarese travel long distances from island to island across open sea in these canoes, and I have myself seen a convoy of some eight making for one of the islands in the central group. Canoes from Car Nicobar to reach this group have to cross a stretch of some forty miles of open sea with only the small island of Batti Malv situated about half-way, and it is by no means uncommon for them to be lost at sea. If caught in the north-east monsoon such cances would be driven towards the south-west, and being caught in the Equatorial Current would be swept to the west and might easily reach the South African coast.

R. B. SEYMOUR SEWELL.

Indian Museum, Calcutta, June 21

[Mr. C. Boden Kloss, director of the Raffles Museum and Library, Singapore, also writes to suggest that the canoe came from the Nicobar Islands and should be compared with the plates opposite pp 80 and 154 of his book "In the Andamans and Nicobars" (London John Murray, 1903) - EDITOR, NATURE.]

## The Magnetic Disturbance of July 21, 1927.

In the Astronomical Column of NATURE of July 30 the suggestion is thrown out that the magnetic disturbance recorded on July 21-22 may, in the absence of any striking spot display, be attributed to an unusually active region on the sun not represented by

a spot, etc.

I submit that the following observation which I made in the late afternoon of July 15 may indeed provide this evidence. At position-angle 130°, that is, for that date near 35° latitude south-east, an immense eruptive prominence rose, splitting at about 15,000 miles altitude into a huge forked formation. each prong reaching ultimately a visible altitude of fully 220,000 miles. Of these two prongs, the more northern one dissolved fairly quickly into invisibility. whereas its southern companion endured a considerable time, showing violent fluctuations of waning and reviving brightness in portions, at varying altitudes. The apparent orifice of the stupendous eruption was fully one day's angle within the sun's disc; and if this is taken into consideration, the longitude occupied by this eruption would just be well past the central meridian on the dates when the magnetic disturbance occurred. From my notes it is also clear that the area from which the prominence rose was before then, and after, much agitated so far as the spectroscope revealed, and showed in its western front a very rough photospheric area, beset with little spots.

# Fall of Temperature during the Solar Eclipse.

IT was recorded in NATURE for July 23, p. 120, that at Bangor the fall of temperature during the total solar eclipse of June 29 was not more than 0° 5 C. At Stonyhurst it is reported that no fall of temperature was observed. At Southport there was a slight fall like that at Bangor. Observations at a position on the sands opposite the northern end of the promenade gave the following result:

. 555 6.0 65 611 6.24 6.30 638 . 10°·2 10° 0 9°·8 9°·7 Totality 9°·8 10°·6 Summer Time . Temperature C.°

Thm clouds all the time intercepted the full effect of the sun's rays. J. R. ASHWORTH.

55 King Street, South, Rochdale. July 29.

# Stephen Hales: Physiologist and Botanist, 1677-1761.1

By Dr. A. E. CLARK-KENNEDY.

TEPHEN HALES was born at Bekesbourne in Kent on Sept. 17, 1677. He was admitted a pensioner of Corpus Christi College, Cambridge, in 1696 and elected a fellow in 1703. At the University he studied theology, chemistry, physics, and astronomy. In 1709 he was appointed minister of Teddington in Middlesex. Soon after, he commenced a long series of researches on the physiology of plants and animals, in which he applied his knowledge of physics and mechanics acquired at Cambridge to the problems of biology.

Hales's first scientific endeavour was to make a complete quantitative investigation of the dynamics of the circulation. "Since we are assured," he wrote, "that the animal fluids move by hydraulic and hydrostatical laws, the likeliest way therefore to succeed in our inquiries into the nature of their motions is by adapting our experiments to those laws." He therefore devised his 'hæmastatical' method, which consisted of the application of the principle of the manometer to animal physiology, and performed a vast number of vivisection experiments of great technical difficulty in the parsonage at Teddington in pre-anæsthetic days. By tying tubes into the arteries and veins of living animals, he was the first man to record bloodpressure. By counting the pulse-rate during life, and then injecting the heart with wax, he computed the circulation rate in horses, cattle, deer, and dogs, showing that in large animals the blood-flow is relatively less than in small. He estimated the actual velocity of the blood-stream in the different arteries and veins. He measured the velocity of the blood in the tissue capillaries by observation with a microscope, and compared it with indirect calculations of the velocity of the blood in those of the lungs. Studying blood-flow in the tissues, he estimated the capillary blood-pressure, and demonstrated vaso-constriction by cold, vaso-dilation by heat. Lastly, by pointing out that the heart responds to increased venous return by increased systolic output, he laid the foundation of the conception now known as 'Starling's Law.'

Hales was essentially a comparative physiologist. Observations on the physiology of plants suggested corresponding experiments on animals. Observations on animals suggested other experiments on the physiology of plants. "About twenty years since," he writes, "I made several hæmastatical experiments on dogs in order to find out the real force of the blood in the arteries: at which times I wished I could have made the like experiments to discover the force of the sap in vegetables; but despaired of ever effecting it, till by mere accident I hit upon it while I was endeavouring to stop the bleeding of an old stem of a vine which was cut too near the bleeding season, which I feared might kill it. Having tied a piece of bladder over the transverse cut of the stem, I found the force of the sap did greatly distend the bladder;

<sup>2</sup> From an address delivered at Corpus Christi College, Cambridge, on June 16.

whence I concluded, that if a long glass tube were fixed there in the same manner as I had before done to the arteries of several living animals, I should thereby obtain the real ascending force of the sap in that stem, which succeeded according to my expectation: and hence it is that I have been insensibly led on to make farther and farther researches by variety of experiments." Applying this method, he found the sap pressure in the vine in the bleeding season to be "five times greater than the force of the blood in the great crural artery of a horse; seven times greater than the force of the blood in the like artery of a dog; and eight times greater than the blood's force in the same artery of a fallow doe."

In the field of physiological botany Hales was certainly a pioneer, as he made the first proper scientific investigation of the flow of sap in plants and trees. He measured the rate of transpiration of water from unit surface area of leaves, the rate of absorption of water by unit area of root surface, and calculated the rate of flow of sap along the stem and branches. He measured the sap pressure in stems with, and in stems without, their leaves and branches. Finding that the sap pressure was upwards in all circumstances, he argued against the current theory of a circulation of the sap, and attributed its elevation to transpiration by the leaves, aided at certain seasons by a force exerted by the roots. Of this work he wrote. "I have been careful in making, and faithful in relating the results of these experiments; and wish I could be as happy in drawing the proper inferences from them." But his theory is now regarded as correct in its main essentials.

Hales also invented the present-day method of studying the growth of plants; that of marking stems and leaves at equal intervals. These experiments of his led him to perform a fundamental experiment on the growth of the bone. "As in vegetables, so doubtless in animals, the tender ductile bones of young animals are gradually increased in every part that is not hardened and ossified; but it was inconsistent with the motions of the joints to have the ends of the bones soft and ductile, as in vegetables, therefore Nature makes a wonderful provision for this at the glutinous serrated joining of the heads to the shanks of the bones; which joining, while it continues ductile, the animal grows; but when it ossifies, then the animal can no longer grow: as I was assured by the following experiment, viz, I took a half-grown chick, whose leg-bone was then two inches long; with a sharp-pointed iron, at half an inch distance, I pierced two small holes through the middle of the scaly covering of the leg and shin-bone; two months after I killed the chick, and upon laying the bone bare I found on it obscure remains of the two marks I had made at the same distance of half an inch: so that that part of the bone had not at all distended lengthwise since the time that I had marked it; notwithstanding the bone was in that

No. 3015, Vol. 120]

time grown an inch more in length, which growth was mostly at the upper end of the bone, where a wonderful provision is made for its growth at the joining of its head to the shank, called by anatomists symphysis." This experiment, usually attributed to John Hunter, born in 1728, was actually performed by Hales some years before that date.

An accidental observation that bubbles of air ascended with the sap was responsible for Hales leaving the comparatively simple problem of the circulation of the blood to attack a much more difficult subject—the chemistry of respiration. Applying his 'statical method,' Hales demonstrated that plants absorb considerable quantities of 'air.' By distilling vegetable substances he showed that plants contained 'air.' He came to the conclusion that 'air' enters into the constitution of plants, and that an important function of the leaves was absorption of this form of nourishment. "It is by this amphibious property of air," he wrote, "that the main and principal operations of Nature are carried on." As Michael Foster pointed out, Hales was the first man to give a clear enunciation of the existence of gases in both a combined and a free state.

True to his comparative physiology again, from absorption of air by plants Hales turned his attention to respiration in man. Mayow had shown that animals absorb a part of the air they breathe, but Hales carried things a step further when he came to the conclusion that respiration in some way modifies the properties of the air left over so as to make it unfit for life and for combustion. Thus he was led to experiment on himself, and to perform the first re-breathing experiment. Taking a well softened bladder, and closing his nostrils, he proceeded to breathe in and out of it. "In less than half a minute," he wrote, "I found a considerable difficulty in breathing, and was forced after that to fetch my breath very fast, and at the end of the minute the suffocating uneasiness was so great that I was forced to take away the bladder from my mouth." Then in an attempt to find "some means to qualify and rebate the deadly noxious quality of these [expired] vapours," he constructed a more complicated form of rebreathing, apparatus with inspiratory and expiratory valves, so arranged that his expired air had to pass through diaphragms of cloth before being inspired again. He could rebreathe the air contained in this apparatus for one and a half minutes only when there were no diaphragms. When, however, these were moistened with a solution of 'sal tartar,' and then replaced, rebreathing could be continued for five to eight minutes. Moreover, the diaphragms increased in weight to a greater extent than he could account for by absorption of water only. If Mayow can be said to have discovered oxygen, surely Hales described carbon dioxide!

Throughout Hales's writings there is no mention of the phlogiston theory. By this silent refusal to follow Stahl, he kept alive the spark of truth that Mayow had lit, to be rekindled more than a century later by Black, Priestly, and Lavoisier If only he had followed Mayow a little more literally, and

conceived, as he had, of different kinds of gases, instead of one 'air' with variable properties, he might well have arrived at a true conception of respiration. Be this as it may, Hales's researches had a great practical outcome in his work on ventilation.

In 1740 troops lay embarked off Spithead for an expedition to America Hales suddenly conceived the notion that large ventilators would be very serviceable in making the air in ships more wholesome. These ventilators were to take the form of large bellows to be worked by hand, which would suck out the foul air from between decks. But he was not alone in this idea. A few months later, Martin Triewald, Captain of Mechanics and Military Architect to the King of Sweden, devised a similar machine. As Hales remarked, "It were indeed a very extraordinary Circumstance, that two Persons at so great a Distance from each other, without getting a Hint of it, one from the other, should happen to hit on inventing a like very useful engine." But it was even more remarkable than this, because at the same time Sutton, a coffeehouse keeper in Aldersgate Street, contrived a method of drawing off the bad air on board ship by means of the cook-house fire. Sutton's invention remained in obscurity, but Hales's ventilators at once attracted the attention of the Admiralty and they were fitted on board H.M.S. Captain, a seventygun man-of-war His ventilators, however, were received with "coolness by some, and contempt by others." But if they did not find favour at first in the Royal Navy, they met with great success in convict ships and the vessels of the slave trade. Five Nova Scotia ships were equipped with them by the Earl of Halifax. Only one slave died in the ventilated ships for every twelve in those unventilated. In a letter to Hales, Captain Thomson wrote as follows: "We found this good Effect from Ventilation, that though there were near 200 Men on board, for almost a Year, yet I landed them all well in Georgia notwithstanding they were pressed Men, and delivered me out of Gaols with Distempers upon them.'

Entering the City of London from the west, the traveller of those days must have been confronted by a curious spectacle. Newgate, the ancient gate of London, had been rebuilt with considerable magnificence. "It consisted of a carriage archway in the centre; on the side, the footpath was continued through it, which supplied a shelter for two or three old women, who fried small sausages for sale: and in the centre of it was an entry to the chief prison of the city: the mendicant prisoners for debt stood within the iron-grated door, vociferating their constant supplication for benefactions to a leathern bag which they drew in as often as it was touched: the upper chambers of the buildings constituted the prisons for felons, for whom a door was opened on the South side adjoining the old wall, and it was from this door that the malefactors were received into the cart for their last journey to Tyburn. Upon the summit was a machine for air, invented by Dr. Hales."

In 1750 a tragedy had occurred during the trial

of malefactors at the Sessions House in the Old Bailey. The Lord Mayor, two judges, and a total of sixty persons had died of the gaol distemper, communicated to them by the felons from Newgate. The aldermen of the City of London, naturally seriously alarmed, consulted Hales, and decided to install ventilators in Newgate to be worked by a windmill erected on the 'leads.' Hales's ventilators were also installed in the Savoy Prison, in the gaols at Northampton, Shrewsbury, Winchester, Maidstone, Bedford, and Avlesbury: in the London Small-pox Hospitals, and at St. George's; also in hospitals at Durham, Winchester, and Bristol, and even at Naples. Later they were introduced into the naval and military hospitals and prisons at Gosport, Portsmouth, and Plymouth So eventually even the Navy was convinced. "God be thanked," writes Hales, they are now come into general esteem for the apparent salutary good effect of them in our fleets, hospitals, etc. In the beginning of the year 1756, the Lords Commissioners of the Admiralty ordered them to be put on board the Royal George, our largest ship: in which the honourable Admiral Boscawen, taking care to have them properly worked, they were found to have the desired good effect, so to refresh the whole air in the ship, as to preserve in good health 850 men: which happy event occasioned their being ordered to be put into the whole fleet."

Wherever Hales's ventilators were installed the air in the wards is said to have been rendered much purer, and the mortality among the inmates from the gaol distemper considerably reduced. But typhus is due to lice, and not to foul air as Hales supposed. No amount of ventilation, however perfect, could have abolished the gaol distemper. Hales's bellows ventilator has gone. Hospitals and prisons are so built in these days that mechanical ventilation is seldom necessary. But his idea of the forcible propulsion of air still persists, and adequate ventilation remains one of the first principles of preventive medicine. Hales must therefore stand for all time not only a great biologist, but also one of the pioneers in public health.

It may seem remarkable that scientific work like this should have been performed by a country parson. But in the study of pure science, though he sought for mechanical explanations always, Hales found confirmation of his faith. "Nature works according to the Laws established at her first Institution," he wrote. "The farther researches we make into this admirable scene of things, the more beauty and harmony we see in them: and the stronger and clearer convictions they give us, of the being, power and wisdom of the divine Architect, who has made all things to concur with a wonderful conformity, in carrying on, by various and innumerable combinations of matter, such a circulation of causes and effects, as was necessary to the great ends of nature." Hales was an ardent parish priest. He made the women of his parish do public penance for irregular behaviour. He prevailed upon the Lord of the Manor to enlarge

the churchyard He arranged for a new parish water supply. He caused a lantern to be erected on the church tower "in which to hang a loud bell to be heard at a much greater distance, not only for the benefit of the serious and the well disposed, but also as a constant memento to the careless, the negligent, and the profane, who with the wicked m Job are but too apt to say, Who is the Almighty that we should serve him? And what profit should we have if we should pray unto him?" He also built a new aisle, and replaced the old wooden tower by a brick one. The money for these alterations was largely raised by the sale of pews, but in addition, Hales contributed £200 himself.

Of his character one of his contemporaries wrote: "He possessed a native innocence and simplicity of manners, which the characters of other men and the customs of the world could never alter; and though he often met with many unworthy objects and uncharitable offices, yet they never once lessened his natural and unwearied disposition of doing good and relieving distress. His knowledge appeared to everybody near him to feed his mind with a nourishment that gave him, in decline of life, and even in its last stages, that vigour and serenity of understanding, and clearness of ideas, which so few possess, even in the flower of manhood: and which he used often to say, he valued as the most perfect of all human pleasures There are two things in his character which particularly distinguish him from almost every other man: the first was, that his mind was so habitually bent on acquiring knowledge, that, having what he thought an abundant income, he was solicitous to avoid any farther preferment in the Church, lest his time and his attention might thereby be diverted from his other favourite and useful occupations. The other feature of his character was no less singular: he could look even upon wicked men, and those who did him unkind offices, without any emotion of particular indignation; not from want of discernment or sensibility, but he used to consider them only like those experiments, which, upon trial, he found could never be applied to any useful purpose, and which he therefore calmly and dispassionately laid aside."

Hales had been elected a fellow of the Royal Society and awarded the Copley Medal, but his reputation as a scientist was now international. In 1753 he was elected one of the eight foreign members of the Royal Academy of Sciences in Paris. Three years later war was declared with France. Hales laboured unceasingly to get Louis XV. to order the installation of ventilators into the French hospitals and prisons where British soldiers were confined. Exerting all his influence through Duhamel and the Duc de Noailles, he was at last successful, and his ventilators were installed into some at least of the French gaols, with, it is said, considerable reduction in the death-rate among the British prisoners. On this occasion the minister of Teddington was heard to say that he hoped no one would inform against

him for corresponding with the enemy!

Hales was now more than eighty years of age.

He had advanced science by fundamental experiments on the circulation of the blood, the flow of sap, the chemistry of respiration, and the growth of bone. By his work on ventilation he had established one of the first principles of preventive He had ministered faithfully to his medicine parish for more than fifty years In the last scene of his active life we see him triumphant, reducing the mortality among British prisoners exiled in the gaols of France. Thus did Hales serve science and humanity, his King and his country. "He delighted to promote the honour of his God by advancing the best welfare of man-

In this employment, blessed with serenity of temper, he calmly met his death as an acquamtance long familiarised to his mind." Stephen Hales died in 1761 in the eighty-fourth year of his age. His monument stands in Westminster Abbey, but his body hes buried under the tower which he had built himself for the church he had loved so well. There is no epitaph written on his grave, but 250 years after the birth of this great son of this College, let us adapt the words John Wesley wrote of him:

"How well did Science and Religion agree in

this man of sound understanding '"

## A National Bureau of Information.

By Dr. S. C. Bradford, The Science Library, South Kensington.

READY means of ascertaining what information has been published on any subject is of the highest importance to every worker in science and technology. As Sir Philip Cunliffe-Lister said in a foreword to the Report of Proceedings of the first Conference on Information Bureaux and Special Libraries, in 1924, "The growth of know-ledge during living memory has been remarkable and its application evident in every direction. Whilst it is generally recognised that knowledge is power, it is none the less true that a considerable proportion of accumulated knowledge is lying dormant and untapped. An immense amount of extremely valuable information is in existence, if only one knows where to find it. The volume of modern knowledge being far beyond the mental grasp of any individual, it becomes a vital necessity to provide a master-key whereby the common

storehouse may be unlocked.'

To this end much bibliographical work has been carried out. Perhaps the earliest suggestion to prepare a comprehensive catalogue of scientific papers was made to the British Association in 1855 by Prof. Henry of Washington. Afterwards, the suggestion bore fruit in the production of the "Catalogue of Scientific Papers" issued by the Royal Society from 1867 and onwards, and later, of the "International Catalogue of Scientific Literature" from 1902, which came to an end with the volume for 1914. Both these indexes covered pure science only. However, the increasing importance of science in every-day life has led to a growing demand for a comprehensive index to the printed records of both scientific and technical activity. Many applications for information or lists of books and papers on special subjects have been received at the Science Library from time to time, and recently such demands have increased in number consider-These applications have been answered so far as possible from the subject-matter catalogue of the books, monographs, and separate papers which are in the Library, and from the extensive collection of bibliographies of every kind that has been gathered together for this purpose; but the labour of preparing such lists is very considerable, and the need for a comprehensive subject-matter card-index from which the desired information could be ascertained immediately has long been realised.

An information service covering the whole field of science and technology has been in process of organisation for some years, and recently the acquisition of a very large collection of subjectmatter index-cards relating to articles and books on science and applied science, published during the period 1902-1914, together with an almost equally large collection of bibliographical slips, which require only to be mounted on cards to bring this index up to date, has placed the Science Library in possession of an exceptionally large card repertory which is now being arranged.

The Library now possesses :

1. A large and increasing collection of the scientific literature of the world, both books and periodicals, which are available for consultation in the Library or for loan to scientific institutions and research associations in Great Britain. (The catalogue of books is in the form of a card-index only, but a list of current periodicals is available, price 1s. 3d. post free.) The Library contains already more than 6000 of the scientific and technical journals recorded in the "World List" and, together with the older series and those acquired after the marking of the List, now possesses more than 7000 such periodicals, which are being added to at the rate of about 1000 periodicals annually.

2. A comprehensive subject-matter card-index to papers in scientific and technical books and periodicals, to be used as a key to recorded information and for the supply of lists of papers on given subjects. This index, which will soon include about one and a quarter million cards, is classified according to the Brussels Extension of the Dewey Decimal Classification, so that all references to information on a given subject can be found in one place under a single classification number, and this can be ascertained from the alphabetical index of subjects.

Bibliographies of special subjects are in course of preparation at very many institutions, but much of the labour expended in this work is only partially effective, because most of these bibliographies are classified on different systems, so that it is impossible to amalgamate them into a single index. To consult them, many volumes and parts must be requisitioned, each different system of classification must be mastered, and then each part of each volume must be looked through separately.

There are, however, a considerable and increasing number of bibliographies, some of them very extensive, that are classified on a single system, the Brussels Extension of the Dewey Decimal Classification. already mentioned, and, as this system is the one which has been most widely used, and is the most convenient for indexing scientific literature on a large scale and in the greatest detail, it has been adopted in the Science Library. This classification, which has been described recently (NATURE, Mar. 19. p. 429), consists essentially of two parts, (a) a more or less logical detailed arrangement of subjects, each class being given a decimal number, and (b) a copious alphabetical index of subjects from which the class numbers can be found without reference to the classification. The new edition of the "Manuel de la classification décimale" about to be published by the Imprimerie de l'Institut International de Bibliographie, Brussels, rue Piers, 101.

The index-cards are classified by writing on each of them the numbers of the corresponding subjects in the Classification, so that, when the cards are put away in their places in numerical order in the index-drawer, all the entries relating to a given subject fall together automatically. Conversely, to find what information is available on a particular subject of inquiry, it is merely necessary to ascertain the number from the alphabetical index and look at the cards bearing that number.

Practically all the available material that is classified by this system has now been gathered in

the Science Library, and it includes:

- 1. The card repertory (1902-1914) of a wellknown continental bibliographical institute that has recently ceased to operate, containing about 350,000 cards.
  - 2. Bibliographia Anatomica.
  - 3. Bibliographia Biologica. 4. Bibliographia Palæontologica.
  - 5. Bibliographia Physiologica.

Bibliographia Zoologica.

These five bibliographies comprise about four hundred thousand printed subject-matter cards from 1896 onwards, published by the Concilium Bibliographicum, Zurich; but the cards for the period 1916-1925 are being acquired gradually.

There are also the following bibliographical periodicals, which are being cut up, mounted on cards, and amalgamated with the above:

Bibliographia Geologica, 1801–1904.

- 8. Optical Society, Transactions, Index to vols. 1-25 and onwards.
- 9. Optician, Review of optical literature, 1927 and onwards.
- 10. Revue de l'Ingénieur et Index technique, published by the Brussels Institute, 1903–1925.

 Bibliographie technique, 1923–1924. Con-

12. Nederlandsch Instituut voor Documentatie en Registratuur, Meddeelingen, 1925 and onwards. 13. Le Mois Scientifique, 1911-1914, 1919.

No. 3015, Vol. 1201

- 14. Technos, 1920-1924.
- 15 Koninklijk Instituut van Ingenieure, Aanwinsten van de Bibliotheck, 1925 and onwards
- 16. Nederlandsche technische wetenschappelijke Literatur, 1924 and onwards
- 17. Revue générale de l'Électricité Documentation, 1921 and onwards.
- 18. Chimie et Industrie Documentation, 1920 and onwards
- 19. Sciences administratives et les tablettes documentaires menuisibles 1925 and onwards
  - 20. Photographic Abstracts, 1927 and onwards.
- 21. Société française de Photographie, Bulletin, 1925 and onwards
- 22. Science et Industries Photographiques, 1925 and onwards.

It is intended that other important bibliographies that are not classified by this system shall be reclassified gradually, so that their entries also can be intercalated in place in the general cardindex with other references to the same subjects

This great subject-matter index will be comparatively simple to understand and rapid to use Having ascertained from the alphabetical index of subjects the number or numbers of the classes that relate to the various aspects of the subject to be investigated, all the cards bearing titles of recorded information that is pertinent will be found together in chronological order under the corresponding numbers.

By this autumn the preparation of this subjectmatter index will have advanced sufficiently for it to be made available to the public, when its extent will be approximately as follows:

Subject		No of Biblio- graphical References	Approximate Period Covered.
Mathematics Physics Geology Biology—		100,000* 15 000 48,000	1893→ 1903→ 1801–1904
General biology Palæontology Zoology Anatomy Physiology		200,000	1896→
Steam and locomotive engineers Electrical engineering. Telegraphy and telephony Motors, transmissive machin	:	39,000 61,000 2,700	·: :
machine tools, and work practice Mining and economic geology Bridges, roads, railways		45,000 30,000 33,500	:
Canals, docks Hygene, public health Water and road transport Aviation	•	10,000 11,000 19,000 4,500	1903→
Communications, transport Chemical technology Metallurgy Building construction	•	19,000 76,000 39,000 10,000	· · ·
Agriculture, economic botany, forestry Other subjects	and .	250,000* 100,000	1919 <del>-&gt;</del> 1903->
Total references .		1,112,700	

\* These sections require reclassification and therefore may not be completely arranged until some months later

For those who are unable to visit the Library, lists of books and papers will be typed from the cards so far as the general work of the Library Photostat copies of articles can also be permits. furnished on payment.

# Obituary.

Prof. Albrecht Kossel.

PHYSIOLOGICAL chemistry has suffered a severe loss by the death of Albrecht Kossel, emeritus professor of physiology in the University of Heidelberg and director of the Institute for Protein Investigation in that city. He was in his seventy-fourth year, and died after a very brief

illness on July 5

Kossel was (with Baumann and Thierfelder) one of the most distinguished pupils of Hoppe-Seyler. After being assistant to the latter at Strasbourg, he spent some years at Berlin, occupied the chair of physiology at Marburg from 1895 until 1901, and then migrated to Heidelberg. A physiologist by training and a medical graduate, he devoted his researches almost entirely to chemical subjects. both as an investigator and as editor of the Zeitschrift für physiologische Chemie for more than thirty years, he was one of the leaders in the new science of biochemistry. His earlier investigations were concerned with the nucleic acids; he recognised xanthine and hypoxanthine as among their constituents, and discovered adenine. The sugar group was detected in yeast nucleic acid (1893) and in thymus nucleic acid (1894), the pyrimidine derivative thymine was discovered in the same

Turning his attention to the simplest proteins of fish-roe, the protamines (first investigated by Miescher), Kossel recognised their high content in arginine and the other amino-acids termed by him "hexone" bases. Thus salmine was investigated in 1896, and in the same year the important aminoacid histidine was discovered by the hydrolysis of histone. Next he worked out the classical method for the quantitative separation of the hexone bases by means of phosphotungstates and silver compounds. Thus at the beginning of the century Kossel had reached a position of pre-emmence by his utilisation of the exact methods of organic chemistry, in contrast to the less precise processes

of older physiologists

Arginase, the ferment which hydrolyses arginine to urea and ornithine, provided perhaps the most physiological of Kossel's investigations, carried out in conjunction with H. D. Dakin, his distinguished English pupil. Later he discovered decarboxylated arginine (agmatine) in herring-roe, and based a most convenient method for preparing that amino acid on the use of naphthol yellow (flavianic acid).

Kossel naturally received many distinctions; in 1907 he presided over the International Congress of Physiology at Heidelberg; in 1910 he was awarded the Nobel prize for medicine. He received honorary degrees from several universities, including Edinburgh, where in 1923 he was recogmised as the leading representative from Germany at the Physiological Congress of that year. He visited London so recently as April last as a delegate to the Lister Centenary Celebrations. Many British friends will mourn his loss. Kossel leaves one son, Walther, the well-known professor of theoretical physics at Kiel, and one daughter.

The words which Kossel wrote of Hoppe-Seyler are peculiarly applicable to himself ready to acknowledge the ments of others, he could not understand attempts to import personal motives into science. . . For years he strove to secure the foundation of separate chairs of physiological or medical chemistry in German universities, in order to ensure the independent development of these subjects." Such was his character; such was his life's work.

## SIR WILLIAM ASHLEY

SIR WILLIAM ASHLEY, whose death we regret to record, was an economist of note He studied history at Oxford and afterwards went to Germany, where he came under the influence of Schmoller. which gave an impetus to most of his later work. For a period he held various university posts in the United States of America, returning to England to found the Commerce Department at the University of Birmingham, where he was professor, dean of the Faculty of Commerce, and later Vice-Principal of the University. On his retirement he settled at Canterbury and had several inquiries in hand, but these expectations were frustrated by a serious illness which terminated fatally on July 23.

Sir William Ashley was a realist in economics. He established his reputation early by his remarkable "Introduction to English Economic History." This book occupies a special place in British economic literature. While it is true that Archdeacon Cunningham had made important contributions earlier in the same field, Ashlev's work had special qualities. He emphasised the comparative treatment of economic development, and showed the general continuity of that of England with the results already arrived at by a number of German writers. The book—considering that it was written in America—may be regarded as in many respects a tour de force. It opened a new field and almost set a new standard for British investigators. Also it opens up an interesting problem. Ashley traced the development of English economic life in the Middle Ages. The effect of the centralising power of the Church was towards a uniformity of organisation and of methods in different countries. With the bursting forth of distinctive national peculiarities at the beginning of the modern period, national diversity replaced uniformity, and one wonders how Ashley's method would have dealt with England of the sixteenth and seventeenth centuries or the period of the industrial revolution-alas, one wonders vainly.

Though Ashley was primarily an economist and historian, he had a great appreciation of scientific method and scientific discovery. This showed itself in an interesting way. When he was establishing the Faculty of Commerce at Birmingham, he was greatly impressed with the idea that the student who looked forward to a career in a manufacturing industry needed not only to know the economic issues involved and the commercial technique, but also something, at least, of the main scientific ideas which lie at the root of the actual manufacturing operations, and in the conditions

of study he made provision for this

One important aspect of Ashley's work was the part he took in public affairs where economic issues were involved More than twenty years ago he took part in the Tariff Reform controversy, and since the beginning of the War he was an able and energetic member of a great number of important commissions and governmental committees Amongst these may be mentioned those on the Cost of Living and the Balfour Committee on Industry and Trade In this way during the last twenty years Ashley spent himself freely, for, as a rule, when he accepted membership of a committee, he himself undertook a considerable amount of research on aspects of the terms of reference, while he was a valuable member in initiating investigations to be carried on on behalf of the committee. He had the gift of seizing what were the central points of an inquiry and of drawing together the data that existed bearing upon them Then (as always happens in any inquiry which is worth making) there were gaps, and he was both fertile and happy in devising plans for bridging these so far as it was possible in the time available. For these reasons a great deal of Ashley's work—and that not the least valuable is known only to a few, and it is fitting that this side of his labours, as well as his better known work, W. R. Scott. should be recorded.

# Mr J. H. REYNOLDS.

Mr. John Henry Reynolds, whose death occurred on July 17 at the advanced age of eighty-five years, may be truly described as one of the great pioneers of technical education in Great Britain. Though his work was wrought chiefly in Manchester, his influence was felt throughout the whole of the United Kingdom, and even beyond the seas, and it is not too much to say that he is to be numbered among those to whose early vision and service we are indebted to-day for the great development in the teaching of technology and applied science during the past forty or fifty years. Mr. Reynolds' work began in days when the need for technical education had not been realised, save by an enlightened few, and he steadily set himself to the task of awakening interest in what he knew to be a thing of vital import to the industries of Great Britain—the provision of the highest instruction and training in science and technology for the equipment of those who are to guide and direct and, by the use of special knowledge, develop industrial work. He was in the highest sense an idealist, and in his early outlook visualised a national system of education which would afford a means of consecutive training from the elementary school to the highest work of the university for students of proved ability and application, however humble their circumstances. That he lived to see the ful-

filment in large measure of his ambitions was due, in part at least, to his own strenuous endeavours and clear vision

Mr Reynolds became secretary to the Manchester Mechanics Institution in April 1879, at a time when, to quote his own words, it "had declined in numbers and influence, and was heavily indebted financially" But under his wise administration, and with the help of generous firms and individuals, the work developed steadily, and in 1902 the present College of Technology building was opened—the direct outcome of his untiring energy, devotion, and far-sightedness through some twenty-three years In 1905 the Faculty of Technology in the University of Manchester was established in the College, and Mr Reynolds became the first dean of the Faculty When in 1912, having attained the age of seventy, he relinquished his task, the College stood as a worthy expression of his ideals and a lasting memorial of his life work, for it had become a centre of the highest type of technological education and research, with a reputation that was world wide.

Mr Reynolds' distinguished services in the cause of technical education were recognised by the Association of Technical Institutions by his election to the presidency of that body in 1913. He also took a prominent and active part in the work of numerous other educational organisations

A fearless fighter on behalf of any cause he espoused, he was yet gentle and considerate in all his dealings with others. He possessed a ready sympathy and a kindliness of heart that endeared him to all whose privilege it was to labour with him. He will be remembered by those who knew him as a man who not only cherished ideals—ideals of truth, human brotherhood, and liberty—but who sought also with untiring zeal to work out those ideals in his daily life.

J. A. Binks.

WE regret to announce the following deaths:

Prof. Alexander Backhaus, formerly professor at Gottingen and director of the Agricultural Institute of the University of Konigsberg, and from 1906 until 1913 director of the Agricultural School at Montevideo, aged sixty-one years

Mr. C. W. Daniels, formerly Director of the London

Mr. C. W. Daniels, formerly Director of the London School of Tropical Medicine and a member of the Royal Society Malaria Commission to India and Central Africa, on Aug. 6, aged sixty-five years.

Dr. Henry Mills Hurd, emeritus professor of psychiatry at the Johns Hopkins University and president in 1899 of the American Medico-Psychological Association, who was editor of the American Journal of Insanity and the Johns Hopkins Bulletin, on July 20, aged eighty-four years.

aged eighty-four years.

Prof. V. Lenher, professor of analytical and morganic chemistry in the University of Wisconsin, known for work on the chemistry of gold, tellurium, and selenium, on June 12. aged fifty three years.

selenium, on June 12, aged fifty-three years.

Dr Erwin F Smith, pathologist in charge of the laboratory of plant pathology in the U.S. Bureau of Plant Industry since 1886, and president in 1910 of the American Botanical Society, an authority on bacterial diseases of plants, on April 6, aged seventy-three years.

## News and Views.

THE Gold Medal of the African Society is awarded for pre-emment services rendered to Africa only five men have received it. The first was the late Sir Hairy Johnston, who as explorer, administrator, zoologist, and writer left a deep mark upon the continent For some years he was the president of the African Society. The second recipient was Sir Alfred Sharpe, who did splendid work as explorer and administrator in Nyasaland and Northern The medal was next given to Sir Frederick Lugard, in recognition of his great achievements in both East and West Africa Since his retirement from the Governorship of Nigeria, Sir Frederick continues to serve Africa as a member of many important committees, as chairman of the Executive Council of the International Institute of African Languages and Cultures, and as member of the Mandates Commission of the League of Nations. Sir Reginald Wingate, Bart., received the medal in acknowledgment of his great career in the Sudan. Now the medal has been given most fitly to Sir Ronald Ross. By this act the African Society pays homage, not only to Sir Ronald personally, but also to all who by their researches into the problems of health in the tropics have wrought such beneficent changes in the conditions of life in Africa.

A PUBLIC appeal for £35,000 for the purchase of 1444 acres of land on Salisbury Plain adjoining Stonehenge has been issued by a Stonehenge Protection Committee with the support of the Prime Minister, Mr. Ramsay Macdonald, Lord Crawford and Balcarres (president of the Society of Antiquaries). Lord Grey of Falloden (vice-president of the National Trust), and Lord Radnor (Lord Lieutenant of Wiltshire). The land upon which options have been secured includes the whole 'sky-line' of Stonehenge and covers the area upon which are situated the huge aerodrome and the huts which now disfigure the site and dwarf the monument If the purchase is effected. these will be cleared away and the land vested in the When it has been added to the National Trust actual site of the monument, which was presented to the nation nine years ago by Sir Cecil Chubb, building in the neighbourhood of the monument or the undue encroachment of the plough will be effectually prevented.

The disfigurement of the Stonehenge area has been made imminent by the development of motor traffic and the increase of the number of tourists visiting Salisbury Plain. Extensive plans for building, indeed, are already in existence. On more than one occasion in recent years, it will be remembered that those who are interested in the protection of the surroundings of the monument from anything that would detract from its unique character and dignity have been alarmed seriously by the nature of proposals for the development of this part of the Plain. That it should be placed beyond the reach of such risks is a matter of even more than national concern. It may confidently be hoped that the

appeal will receive the strong support it deserves. Contributions should be made to the National Trust (Stonehenge Fund) and addressed to the Secretary, 7 Buckingham Palace Gardens, London, S.W.1.

The ether is becoming seriously overcrowded with radio waves. Two or more stations having nearly the same official frequency often 'jam' one another in an ordinary receiving set. The problem of inventing a simple method of cutting out the interfering stations is therefore one of great importance to the radio engineer. In a paper read by G. G. Blake to the Radio Society of Great Britain on May 25, a description is given of a method of improving the selectivity of a receiving set by means of ordinary sound resonators. The results obtained were most encouraging Even when several stations were working with considerable mutual interference and bad atmospheries were present, it was found possible to isolate the selected station by means of a sound resonator. It is concluded that there is no reason why many more frequencies could not be selected for stations in the wave bands at present employed for broadcasting. The author suggests that by the use of a hot wire microphone and a number of sound resonators each tuned to a different station, all the signals could be heard or recorded simultaneously. He points out that the hot wire microphone or thermotelephone receiver was described by Sir William Preece to the Royal Society in 1880. It consists of a tightly stretched fine platinum wire fixed at one end and attached at its other extremity to the centre of a diaphragm. The wire is heated by a current from a battery and the expansion or contraction of a wire in response to words spoken towards a microphone in series with it cause the diaphragm to vibrate.

In his presidential address to the Devonshire Association for the Advancement of Science, Literature and Art, delivered on July 19, Mr. W. C Dampier Whetham took as his subject "The Newtonian Epoch, 1685-1920" Mr. Whetham sums up as the two most important consequences of Newton's labours, the establishment of the validity of terrestrial mechanics in celestial spaces, and the removal of philosophical dogma from the basis of natural science rational outlook was carried over into chemistry by Lavoisier and formed the basis of the work of Dalton. Joule, Kelvin, Darwin, Young, Clerk Maxwell, etc., in the nineteenth century. The discovery of Neptune gave final proof to Newton's theory, and the science of spectrum analysis extended terrestrial chemistry to the heavenly bodies. Towards the end of the nineteenth century a new era began with the discovery of X-rays, electrons, radio-activity and atomic disintegration. The distribution of energy in the radiation from a hot body led to Planck's quantum theory, and this was used by Niels Bohr for the construction of a new and brilliant theory of the atom. Concurrently a new view of the ether developed, giving rise to the revolutionary outlook on space and time put forward by Einstein in 1905. This was summed up by Minkowski in the conception of a space-time interval, which, with the principle of equivalence, gave in the hands of Einstein the relativity theory of gravitation. In the two directions of the quantum theory and the theory of relativity, physics seems to be breaking away from the dynamics of Newton. "The new vision of Nature is utterly unlike the materialistic nightmare which afflicted some who suffered from ill-digested Newtonian philosophy. We must hope that a future Newton may reconcile the discrepancies, and bring the laws of these new phenomena into subjection to the human mind."

THE fourth International Congress of Theoretical and Applied Limnology will be held in Rome this year, and a full programme has been arranged covering the period from Sept 18 to Oct 3. The congress will be divided into four sections, dealing with physics and chemistry, geology and hydrography, biology, and applied limnology, respectively The first week will be spent in Rome, during which time lectures and papers will be given and opportunity will be afforded for visiting the Limnological Exhibition, the Royal Central Laboratory of Hydrobiology, the Royal Fish Breeding Establishment, and the Zoological Gardens. Receptions will also be given on the Capitol and at the Royal Italian Geographical Society. The remainder of the programme offers some very enjoyable excursions. Two days will be spent at Naples, where the visitors will be received at the Zoological Station and at the University. The congress will conclude with a most attractive itinerary to the Hydrobiological Stations situated amongst the delightful scenery of Lakes Garda, Como, and Maggiore, while nights can be spent en route at Perugia, Verona, and Milan. The congress will end on Monday, Oct. 3, at Lake Maggiore. Members of the congress on payment of the sum of 50 L. will be entitled to reductions on the Italian railways, and to cards of admission to all the meetings and excursions. They may be accompanied by members of their families for a fee of 30 L. All communications and inquiries relative to the congress are to be addressed to the Segretaria del Comitato Esecutivo at the R. Laboratorio Centrale di Idrobiologia, piazza Borghese 91, Roma (9).

By an Order of the Committee of Privy Council, Sir Hugh K. Anderson (Master of Gonville and Carus College, Cambridge) and Prof. T. R. Elliott (Director of the Medical Unit, University College Hospital, London) are appointed members of the Medical Research Council into the vacancies caused by the retirement of Sir Frederick Andrewes and Sir Cuthbert Wallace.

On Aug. 8 Prof. Henry Fairfield Osborn completed his seventieth year. The event has given his many friends the opportunity to present him with a Queen Anne cup of beautiful design and an illuminated manuscript with their greetings and signatures. At a reception to be held later, the surplus of the fund subscribed will be presented to Prof. Osborn for the advancement of his research work. We offer congratulations on the successful labours of the past and best wishes for the future.

No. 3015, Vol. 1201

From a notice just issued by the Ministry of Agriculture and Fisheries, we learn that in accordance with a recommendation of last year's Imperial Conference, an Imperial Agricultural Conference will be held in October next. It may be recalled that the Imperial Conference laid great stress on the potential value of co-ordination between the research agencies in various parts of the British Empire. Many will be interested to see what concrete shape co-ordination will take. There is as yet little co-ordination within Great Britain, though the need for it positively glares at one from the pages of a recent publication by the Ministry, "Research and the Land." In the words of the adage, "charity begins at home."

The Washington Science Service Daily News Bulletin contains a brief comparison of the ancestry of present-day American statesmen with that of statesmen in Revolutionary times. It is found that the law-making of the United States is still chiefly in the hands of 'Nordies' as it was in Revolutionary days. Mr. Frank L. Babbott finds that 90 per cent. of the statesmen who met in Philadelphia to frame the constitution were English, Scotch, or Irish, while in the last Senate 81 per cent. were of similar descent, although the numbers are about twice as great. Of the others, several were partly and two wholly of French origin, two were Swedish, and one Norwegian.

THE series of observations of the sound of the firing of heavy guns at Shoeburyness, to which reference was made in Nature of July 23, was continued on Aug. 3, when ten rounds were fired. The time of firing of each round was broadcast by the B.B.C. from Daventry. So far, reports have been received from sixteen observers, of whom five only heard the sounds. Of these five, four were located on the east coast, from Clacton to Ipswich, and the fifth was located at Isleworth. Four observers in London and seven observers distributed over a wide area, state that they failed to identify the sounds of firing. The reports so far received are not sufficient to define with accuracy the zones of audibility. Instrumental observations were obtained at the Universities of Birmingham and Bristol. At Birmingham the records showed that the time of transit of the sound waves from the gun to the instruments averaged about 12 min., compared with the time of transit of 11 mm. 51 sec. on July 9, and 12 mm. 16 sec. on July 13.

From time to time interesting accounts of the lives of the earlier American chemists are published by Dr. E. F. Smith, of the University of Pennsylvania, and one of his recent sketches concerns James Blythe Rogers (1802–1852), the eldest son of Dr. P. K. Rogers, an apothecary of Baltimore The latter became professor of chemistry at the William and Mary College, and it was at this college that J. B. Rogers and his three brothers, William, Henry, and Robert, all men of science, were educated. After a brilliant college career James studied medicine, and received his doctor's degree from the University of Maryland in 1822. He was not pleased with his profession, however, and so he became the superintendent of an

extensive chemical factory in Baltimore Father and sons were in regular correspondence, and the many quotations which are taken from their letters are very illuminating. Each became eminent in his particular branch of science. James being well known as a competent analyst. He did most of his work in connexion with the geological surveys carried out by his brothers William and Henry The chemical factory with which he was at one time associated derived great benefit from his labours, as he was ever ready to apply his knowledge to industrial purposes.

THE Report of the Fuel Research Board for 1926 (H.M S.O. 1s. 3d. net, pp. 62) reveals how well based is the research into the fuel resources of Great Britain which has been developed in the last few years. This work is carried on not only at the Government station but also at various university and other institutions, where independent workers receive assistance from State funds Much of what is contained in the Report has been published elsewhere, but some information is new. An apparatus devised for determining the reactivity of coke is described Perhaps the section dealing with coal treatment by carbonisation at low temperatures and by hydrogenation will be read with most general interest. The opinions as to commercial success attained by such processes are guarded but hopeful. A welcome feature is the announcement of an arrangement whereby the Gas Light and Coke Co. undertakes to operate a setting of the cast-iron vertical retorts devised at Greenwich under the commercial conditions of a modern gasworks for a period of years. Such an arrangement ensures for the process a commercial trial under the most favourable economic conditions, but nevertheless a searching trial alongside carbonisation plant which must and does pay its way. Hydrogenation of coal is regarded as still more immature from a commercial viewpoint, but it is pointed out that even if the process cannot compete with imported natural his at present prices, conditions may change at any time. It is of great importance that information should be available of any process for producing liquid fuels from home sources. No one can read the Report without feeling reassured as to the measure of scientific effort in Great Britain to make the best use of native fuels.

Part I. (Medical) of the Registrar-General's statistical review for 1926 of Great Britain has recently been issued (London · H.M. Stationery Office. 15s.). From this it appears that the birthrate for the year 1926 was 17 8 per 1000 population. Excepting the rate of 17·7 in 1918, the last year of the War, which at that time was regarded as phenomenally low, that for 1926 is the lowest recorded since the establishment of civil registration in Great Britain. In view of the continued decline during the first half of the current year it is probable that the rate for 1927 will be lower than that for 1918 The crude death-rate was 11 6 per 1000 population, and was equal to that of 1923, the lowest on record. In 1924 and in 1925 the rate was 12·2 per 1000. The pro-

visional birth- and death-rates and infantile mortality in 1926 for some other countries were as follows:

	Birth- rate	Death- rate	Natural Increase	Intantile Wortality
Sweden . England and V Switzerland (1 France Belgium Germany Norway . U.S.A . Scotland Holland Hungary . Italy (1925)	16 9 17 8 18 4 18 8 19 0 19 5 19 7 20 1 20 9 23 8 26 7 27 8	11.8 11.6 12.2 17.5 12.9 11.7 10.6 12.1 13.0 9.8 16.5 16.8	5 1 6·2 6 2 1 3 6 1 7 8 9 1 8·0 7 9 14·0 10 2 11 0	70  98  101  73 83 61 168 119

Thus, the birth-rate in England and Wales has now fallen below that of France, and with the exception of that of Sweden, is the lowest of the principal European countries. On the other hand, the general death-rate and the infantile mortality are low compared with the rates prevailing in most of the other countries

THE Pathological and Bacteriological Laboratory Assistants' Association is holding a conference at Cambridge from Aug. 22-26, under the presidency of Prof. H. R Dean. A scientific programme has been arranged for each morning, whilst the afternoons will be reserved for excursions. The conference will be opened by the Vice-Chancellor of the University, the Rev. G. A Weekes, at 10.30 A.M. on Monday, Aug. 22, and the opening ceremony will be followed by a lecture on Cambridge, by the Vice-president, Mr. W. A. Mitchell: in the afternoon the Association will be entertained in the Fellows' Garden, Downing College. On the four following mornings, papers and demonstrations will be given in the Department of Pathology of the University. These cover a wide range of subjects, among which the following may be noted: a standard dietary for laboratory rabbits and gumea-pigs, by E Pleasance; the manufacture of smallpox vaccine as carried out in the laboratories of the Shanghai Municipal Council, by A. E. P. Grimmo; cinema films of infusoria. spirochætes, trypanosomes, etc., by G Harper; virulence tests in the identification of B. diphtheriæ, by S. J. Denyer; the preparation of plague vaccine, by F Leeson; difficulties encountered in the differentiation of paratyphosus A, B, and C, by S. J. Denyer; tissue cultivation technique and pulsating heart cultures, by V. C. Norfield, the cultivation of protozoa, by W. Cooper and W. J. Muggleton. This selection from the list of papers and demonstrations on the programme gives a good idea of the standard of knowledge and technique required of a modern laboratory assistant. The Conference dinner will be held in the hall of Trinity Hall on Thursday, Aug. 25, and during the evening the Woodhead Medal will be presented to Prof. J. Lorrain Smith. The meeting concludes with demonstrations on the morning of Friday, Aug. 26.

THE annual report by the Conservator, Sir Arthur Kerth, on the Museum of the Royal College of Surgeons of England has recently been issued. The Conservator has reported on many discoveries of human remains, and several of the skulls have been added to the Museum. The odontological collection is once more on view, after extension of the room, with many additions. The pathological, osteological, teratological, and physiological collections have received numerous additions, many old specimens have been re-mounted, and some re-cataloguing has been undertaken. A valuable collection of books relating to the history of surgical instruments has been presented by Mr. J. Barry Hopkins Several pieces of research work have been carried out in the Museum, eg one on the lymphatic system of fishes by Mr R. H. Burne. The Conservator acknowledges the assistance he has received from the sectional curators and voluntary helpers.

The International Hydrographic Bureau at Monaco has issued as *Special Publication* No. 18 a list of litesaving stations of the world with their equipment and exact geographical positions. It has been compiled from Sailing Directories and other official documents. The text is in both English and French. When notice of errors, omissions, and changes are received, the Bureau will issue a corrected list and hopes to arrange for a translation into all maritime languages. The list should prove valuable to ship masters, marine insurance companies, steamship companies, and others. Its price is 30 cents.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—A lecturer in mechanical engineering in Swansea Municipal Technical College—The Director of Education, Dynevor

Place, Swansea (Aug. 20). An inspector of weights and measures and two qualified assistants to the Chief Inspector of Weights and Measures of the Weights and Measures Department of the Essex County Council-The Clerk of the County Council, Shire Hall, Chelmsford (Aug. 22). A Statistical Director of the Cotton Trade Statistical Bureau now being established by the Manchester Chamber of Commerce—The President of the Manchester Chamber of Commerce, Manchester (Aug. 24) An assistant lecturer on machine design in the University of Birmingham - The Secretary, The University, Birmingham A lecturer in agricultural chemistry in (Aug. 24). the University of Reading—The Registrar, The University, Reading (Aug. 26). A professor of anatomy in the University of Durham College of Medicine-The Registrar, University of Durham College of Medicine, Newcastle-upon-Tyne (Aug. 31) A lecturer in biochemistry in the Physiological Department of the University of Birmingham—The Secretary, The Univer-A senior lecturer in sity, Birmingham (Sept. 21) physiology in the University of the Witwatersrand, Johannesburg—The Secretary, Office of the High Commissioner for the Union of South Africa, Trafalgar Square, W.C.2 (Sept. 26). A senior demonstrator in the Department of Physiology of the University of Otago, Dunedin, New Zealand-The Registrar, University of Otago, Dunedin, New Zealand (Oct-20). An agricultural economist in the Agricultural Department of the Tanganyika Territory—The Private Secretary (Appointments), Colonial Office, 38 Old Queen Steet, S.W.1 (Nov. 1). An assistant inspector of plants and produce in the Lands and Forests Department of Sierra Leone—The Crown Agents for the Colonies, 4 Millbank, S.W.1 (quoting M/15528).

## Our Astronomical Column.

COMET NOTES.—Miss J M Vinter-Hansen has computed the following orbit of Reid's Comet (1926 VII.=1927 b) from observations made at the Cape Observatory on Jan 26, Feb. 3 and 8 (Copenhagen Circ., 159):

$$\begin{array}{cccc} \mathbf{T} & 1926 \ \mathrm{Dec.} \ 30\cdot676 \ \mathrm{U.T.} \\ & \omega & 225^{\circ} & 5 \ 48' \\ & \Omega & 108 & 50 \ 96 \\ & \imath & 83 & 39\cdot69 \\ \end{array} \right) 1927 \ 0 \\ \log q & 9 \ 87818 \\ \mathrm{O-C} & \begin{cases} \Delta \lambda_2 \cos \beta_2 = +0\cdot52' \\ \Delta \beta_2 & = -0\cdot08 \\ \end{cases}$$

The large residual in the middle place suggests possible departure from a parabola. The comet may still be observable: the following ephemeris for 0<sup>h</sup> is by A. V. Nielsen from the above orbit:

		R.A.		NI	Decl.

# Research Items.

THE ROCK SHELTER OF LA GENIÈRE -MM C. Gaillard, Pissot, and C. Cote describe in L'Anthropologie, T 37, Nos. 1-2, the results of an exploration of the rock-shelter at Serrières-Sur-Ain, one of a number of rock-shelters and grottoes on the Ain examined in 1903, in which the traces of occupation then discovered were attributed to the early neolithic. Beneath the level opened up in 1903 has now been found the evidence of an earlier period which the authors assign to the end of the Magdalenian. This level of occupation has produced a relatively small number of animal remains, including Bison priscus, Cervus tarandus, species of goat, ox, and pig, and Canis vulpes, a human skull—of a child—and a large number of examples of a microlithic industry in which sub-triangular forms are numerous Of bone points, four only were discovered. An engraving of a reindeer and another of a bison present a very close analogy with the paintings of the Font du Gaume The australoid or negroid characters of the skull suggest that this is a race of late Magdalenian date descended from the Grimaldi people and the culture a specialisation of Magdalenian rather than Azilo-Tardenoisian. It is possible that this same race was responsible for the art of the Font du Gaume, and it is suggested as probable that its culture is to be attributed to a strong infiltration of the Capsian of North Africa.

THE INHERITANCE FACTOR IN PNEUMONIA -An interesting study of a family which is subject to pneumonia and other respiratory diseases has been made by Prof. Raymond Pearl (Annals of Eugenics, vol. 2, p. 1) It is usually assumed by medical clinicians that pneumonia is merely the result of a chance bacterial infection, but here is a working family living under fairly good conditions and showing a far higher incidence of pneumonia than their neighbours or others living in similar conditions. Every child in this family of thirteen had had pneumonia, one having had it twice and one three times, and seven had died of it. They could not have im-mediately infected each other because of the time intervals between attacks. By a careful study of the pedigrees of father and mother, Prof. Pearl shows that the father's family stock had a high incidence of tuberculosis, fertility somewhat above the average, and respiratory diseases in childhood; while the mother's family showed low fertility and very low infant mortality. The evidence as a whole points strongly to an inherited constitutional condition as the cause of the very high incidence of pneumonia in this family. The same probably applies to bacterial diseases generally, some individuals and families mheriting greater susceptibility than others. But the nature of these differences in power of resistance to a specific bacterium and the manner of its inheritance are as yet very inadequately known. Further knowledge should make a genetic analysis possible, as has been done with susceptible and resistant strains of certain cultivated plants.

Plague in South African Institute for Medical Research (Publication No. 20, vol. 3, pp. 85-256) has recently been issued dealing with the plague problem in South Africa. Dr. Harvey Pirrie contributes notes on veld rodents susceptible to plague, illustrated with eight plates, and on plague infection among these rodents. A hitherto undescribed bacterial disease has been found in the gerbille. Experiments have also been carried out with vaccines, sera, etc., on the prophylaxis and treatment of plague. Dr. Ingram discusses plague

investigation from an entomological aspect, and Dr. Alexander Mitchell contributes a historical summary on plague in South Africa

AGRICULTURE IN INDIA.—Dr. Clouston, in a "Review of Agricultural Operations in India, 1925-26, surveys in detail the conditions throughout the country, and includes reports and statistics on a number of crops, soil investigations, animal nutrition and vetermary science, engineering, insect pests and plant diseases, together with a list of the agricultural publications during the year (Calcutta: Government of India Central Publications Branch. 2.6 rupees; 4s. 3d.). On the whole, in spite of an uneven distribution of rain, the season was fairly good. Much progress has been made in the seed selection and hybridisation of rice and wheat, and the particular importance of phosphate manuring for the former crop in dry seasons established. Considerable organisation and legislation has been necessary in the case of cotton, but experimental work, such as spinning tests at the new technological laboratory and the development of a fumigation scheme for use on imported cotton, has been successfully carried out. Important advances have also been made in the technique of breeding sugar-cane, and improved methods of cultivation and manuring are yielding good results. Research on fundamental soil problems is being carried out by the various agricultural departments The soil in general is very deficient in nitrogen owing to prolonged cultivation without the addition of manure. Organic materials, such as cattle or green manures, are the most suitable, much that could be used with advantage being at present exported. Economical modifications of the original method of making artificial farm-yard manure have already been devised. A new line of work, which is yielding interesting practical results, is the determination of the feeding properties of pasture grasses and the relative value of Indian fodders. The serious rinderpest disease of cattle has been effectively diminished by the widespread use of preventive inoculation, but the loss incurred during the year under review was extremely serious, and further investigations with the view of conferring permanent immunity are being undertaken. The co-operative movement started by the Government in 1904 is now working in touch with the agricultural departments, but further extension is still needed as, for example, in the organisation of the marketing of produce. Useful work in this direction has been done by the cotton-sale societies in Bombay and the milk societies m Bengal.

Petrified Forests.—In the June issue of the Scientific Monthly Miss Winifred Goldring, of the New York State Museum, describes the oldest known petrified forest, located near the village of Gilboa in the Catskill Mountains. The first discoveries were made in 1869, but it was not until 1920 and the succeeding years that material was brought to light in sufficient quantity to enable the nature and extent of the forests to be reasonably determined. The fossils belong to the Upper Devonian horizon. During this period the Catskill Mountains formed the low shore-line of a shallow sea. At the present time the fossil trees are found on three distinct levels, indicating that the swampy shore-line was very unstable. Gradual submergence of the coast carried the trees beneath the water and sediment piled over their trunks. When the deposits accumulated the forest again crept down to the water edge. Evidence shows that three successive forests flourished here, were

submerged and buried. These Gilboa trees in general appearance must have resembled the tree ferns of the tropics at the present day. They were, however, seed ferns or Pteridosperms, standing in a position between the tree ferns and the higher seed plants. A new genus, Eospermatopteris, has been created for the Gilboa forms, and two species, E. textilis (Dawson) and E. erianus (Dawson), have been distinguished The outer part of the cortex of the stem is the only part of the structure to any extent preserved, the interior parts having been washed out and the structunes filled with sand. The cortex consists of interlacing strands of sclerenchymatous tissue, and the outer surface is marked with shallow ridges and furrows, in some cases giving the effect of a bark. These trees were probably 25 ft. to 40 ft. high and bore fronds from 6 ft. to 9 ft. in length, on the dichotomous tips of some of which were borne the seeds The bulbous stem bases were undoubtedly buried in the swamp mud as the roots were not heavy, and otherwise the trees would have had no adequate support. Foliage was light and much looser than in the tree ferns of to-day. The lycopod-like trees (Protolepidodendron) also grew in small numbers in the

VERTICAL DISTRIBUTION OF PLANKTON.—Mr. F. S. Russell (Biological Reviews, vol. 2, No. 3, pp. 213-262, 1927), in a very able and exhaustive article, reviews the present position of the problem of the vertical distribution of planktonic organisms begins by surveying the possible controlling factors in the vertical distribution of plankton, such as light, temperature, winds and currents, pressure, salinity, chemical constitution of the sea water, and so on. The author next summarises the known facts of the vertical distribution of planktonic organisms themselves, and concludes that each plankton animal has its own vertical zone, varying for each species and for individuals of different ages and stages of development, and even for different sexes. The type of distribution for any one species may vary from place to place, season to season, and day to day. In fairly homogeneous waters, light intensity may be the prime factor governing vertical distribution, though other factors such as temperature and salinity, rate of movement, and distribution of food must not be ignored. The author then deals with the results obtained by experimental work on planktonic organisms in order to discover how far the observations in the field are borne out and supplemented in the laboratory. He rightly points out that field work should always precede laboratory experiment in order that a proper interpretation of laboratory actions should be possible. In the closing section of the article the author discusses mainly the evidence that light is the most important controlling factor in the vertical distribution of marine planktonic animals. The article concludes with an exhaustive bibliography.

GENETICS OF POLLEN TUBES.—A new gene mutation of Datura Stramonium called tricarpel is being studied by Drs. Buchholz and Blakeslee (Proc. U.S. Nat. Acad. Sci., vol. 13, p. 243). By making various crosses between tricarpel and normal and studying the pollen tubes as they grow down the style, it is found that the factor for tricarpel suffers a considerable amount of elimination through slower growth and also through bursting of the pollen tubes as they pass down the style. The latter process occurs more frequently in pollen tubes of the tricarpel type. When this type is self pollinated, more than half the pollen tubes are abnormal in appearance, and the rate of growth of the normal pollen tubes is slower, although the percentage of pollen germination is

essentially the same as in the type. This gametophytic selection is believed to be an important evolutionary factor. Pollen tube growth has also been studied in the transcription self-sterile plant, Lythrum salicaria, by Mr. D. Kostoff (l.c., p. 253). It is found that germination takes place equally well in all pollinations, but that the rate of growther of the pollen tubes is much retarded by 'illegitimate' pollination, i.e. by putting the wrong kind of pollen on a particular stigma. With 'legitimate' pollination the curve of growth of the tubes is symmetrical, with decided acceleration in the later stages. It has already been shown in self-sterile tobacco that in moompatible matings the pollen tube growth is so slow that the flower falls before the pollen tubes reach the ovary

THE PHYSIOLOGY OF FRUIT TREES.—Two points of general interest emerge particularly from Dr. T. Swarbrick's first paper, under this general title, which is published in the Journal of Pomology and Horti-cultural Science, vol. 6, No. 2, June 1927. His own observations, as also his extensive citation from the literature, make it clear that there is a very interesting phenomenon presented by the temporary disappearance of starch from the phloem of broad-leaved trees, which takes place early in the spring. Usually this is ascribed to a fall of temperature, but Dr. Swarbrick directs attention to Prof. Chandler's warning that the same phenomenon is reported from the genial Califorman spring climate as from the fruit trees of the regions, with hard winters, in the east of the United States. Similarly, Dr. Swarbrick found in one- to fiveyear-old apple branches at Long Ashton, near Bristol, a disappearance of starch from the cortex and phloem in the middle of January, followed by its reappearance at the end of March Dr. Swarbrick also reports that the formation of new xylem from the cambium in the spring begins at the distal end of the apple shoots in the spring, its commencement being associated with the position of the swelling buds. In apple trees, xylem formation was at least three weeks later m the four- than m the one-year-old shoots, whilst on the one occasion in which a standard plum tree was cut down, on the date of cutting, June 15, 1926, no xylem was forming in the trunk at eighteen inches from the ground, although several rows of xylem elements were present in the one-year-old shoots. These observations confirm and extend the work of the East Malling station published in a previous number of the same journal.

A Cambrian Fish.—In the fifteenth biennial report of the Vermont State Geologist, recently published, Dr. William L. Bryant describes the impression of a small fossil from the Cambrian shale of Franklin County, Vermont, U.S.A., which he considers may prove to be the dermal tubercle of a primitive fish. It is an ellipsoid plate 3 min. in length, truncated at one end. Its outer face is ornamented with rows of tubercles, which radiate from a point near the truncate border. Dr. Bryant compares it with the polygonal head-plates of the Cephalaspids, and proposes the name *Eorchthys howells* for the supposed fish to which it belongs.

Some Helicinne from Mexico and Texas.—Dr. Pilsbry has been studying "The Structure and Affinities of Humboldtiana and related Helicid Genera of Mexico and Texas" (Proc. Acad. Nat. Sci. Philad., vol. 79). The group of belogonous helices (Helicine) which comprises these genera seems to be as widely distributed in America as in the old world. No doubt the group became established in America in Mesozoic times, and the evolution of its members

has been along various widely divergent lines. The anatomy of Humboldtiana and its allies Lysmoe. Leptarionta, and Tryonigens is fully described and illustrated with text figures and four plates. The representations of the enlarged surface sculpture of the shells are especially well done.

DECLINATION CHANGES IN GREAT BRITAIN -The Meteorological Office has published as Geophysica Memoirs, No. 35 (price 3s 6d net), "A Comparison of the Records from British Magnetic Stations Underground and Surface," by Dr. C Chree and R E. Watson The purpose of the work was to find to what extent the changes of magnetic declination in the south of England agree with those in other parts, particularly the mining areas, and below ground as well as above. Since 1918 two-hourly values of the declination, at Kew until the end of 1924, and since then at Abinger, have been supplied to certain journals for the use of mine-surveyors, henceforward they are to be replaced by hourly values The present investigation indicates that on quiet days these values fairly represent the changes of declination throughout Britain, and that there is no appreciable difference in the changes below ground. On disturbed days, however, the changes of declination, both regular and irregular, increase in size as we go north, on highly disturbed days, or even on quieter days in the case of short period changes, the increase with latitude is rapid by 50 per cent at Eskdalemuir, and more than twofold at Lerwick in the Shetland Isles

LIGHT QUANTA —A recent paper communicated by Prof M Planck to the Franklin Institute (Die Naturwissenschaften, June 30) contains some of the views of this eminent theoretical physicist on the trend of modern work. In his opinion, the existence of quanta was definitely proved when, in order to obtain agreement with the results of experiment, it became necessary to supplement the fluctuations in the energy of black-body radiation predicted by classical theory, by other fluctuations, also based on considerations of entropy, which required the presence of discrete units of energy. He regards the partial coherence of quanta which is needed to account for interference as connected in some way which has still to be specified with the classical contribution to the fluctuations, and in concordance with other relations of general mechanics and atomic physics, he looks upon radiant quanta as having an extension in the generalised space of the theory of relativity. Prof. Planck believes that the most important problem awaiting solution at the present time is that of the relation between the corpuscular equations and the wave equations in the most general case, since this is needed to connect the mechanics of a particle moving in a path of large curvature with the properties of radiation of high frequency.

Spectrometer Measurements of Soft X-Rays—There is a short paper by J Thibaud in the Comptes rendus of the Paris Academy of Sciences of July 4, in which he describes a grating spectrometer suitable for work in the soft X-ray region. The radiation produced by election bombardment of a suitable target is limited by fine slits, and then analysed at grazing incidence with one of Prof R W Wood's glass gratings, with 25,000 lines to the inch. One plate which has been reproduced shows the Ka line of carbon in three orders, as well as a sharp K line of oxygen. Apparently the success of the method is due to a high efficiency of conversion of kinetic energy of elections into characteristic radiation of about 30 Å.U, as the necessary exposures of the carbon line could be made on oiled plates in minutes, five

with a dissipation of only ten watts in the X-ray tube It is claimed that the wave-length measurements of the  $K\alpha$  lines of oxygen and carbon, and of the  $L\alpha$  line of non and the  $M\alpha$  line of molybdenum have been made with a relative accuracy of 0 1 per cent, and an absolute accuracy of 0 5 per cent.

EXPLOSION OF LEAD BROMATE —A serious explosion resulting in two deaths is reported by the Chemker-Zeitung to have been caused at Seelze near Hannover on May 26 by the grinding of lead bromate in a mortar. The salt, which hitherto had been prepared from lead carbonate and bromic acid, was on this occasion precipitated from solutions of potassium bromate and lead acetate, and had been well washed on a filter and dried in the oven at 70°-80° C. Grinding 1 kgm of it in a mortar caused a very violent explosion and considerable damage was done.

HARDENING STONE -The method of hardening calcareous stone by treating it with a solution of silicate of soda, discovered by Kuhlmann nearly a century ago, has at various times been used to harden the surfaces of roads, but the results obtained have varied so much with the stone used, the method of application of the solution, and the weather conditions at the time, that it has fallen into disfavour Recently, however, both in Great Britain and in France, attention has been again directed to the method, and in the issue of the Bulletin de la Société d'Encouragement pour l'Industrie nationale for May, M. R Feret, head of the laboratory of Ponts et. Chaussées of Boulogne, gives an account of the observations he has made on the nature of the hardening process and the influence on it of the conditions under which it takes place. His solution contained 24 9 per cent. of SiO<sub>2</sub> and 7 3 per cent. of Na<sub>2</sub>O and was used on rocks of many kinds. He concludes that the hardening process is due to adsorption of the silica at the surface of the stone in a gelatinous form which slowly becomes hard and insoluble. The process is facilitated by drying, by dialysis in the stone, and by the action of the carbon dioxide in the air.

PULVERISED FUEL AT SEA.—Now that the use of pulverised coal has been successfully applied in land boilers, its adoption in marine boilers is thought by some to be only a matter of time. The importance of the subject was referred to in a recent paper, "Pulverised Fuel tor Marine Pulposes," by Engineer-Captain J. C. Brand of the Australian Navy, read to the Institution of Naval Architects at Cambridge, and by various speakers who took part in the discussion Capt. Brand dealt with the practical problems involved and the economy of the system, and gave some drawings of typical installations. For certain services the fuel would be pulverised ashore and conveyed by piping into the ships' bunkers, but in other cases ships themselves would be fitted with the necessary pulverising plant With the improvement in combustion resulting from the burning of the coal in the form of very fine dust, it was stated that a vessel could go 15 per cent. to 30 per cent. farther with the same weight of fuel as compared with the distance she could steam with mine coal. Then, too, with pulverised fuel there is a great reduction in the number of firemen. There are to-day many types of pulverising mills, conveyors, burners, etc. As regards the dangers of using pulverised coal, these have been greatly exaggerated in the same way as were the dangers of oil fuel. So long ago as 1917, Capt. Brand carried out experiments for the Naval Board, Commonwealth of Australia, and in his paper gave the results of tests made in H.M.S. Sealark.

# Chemistry in 'Iraq and Persia in the Tenth Century A.D.

AN important communication with the above title appears in the Memoirs of the Asiatic Society of Bengal, vol. 8, No 6, pp 317-418 (1927), the authors being Principal H. E. Stapleton, of Presidency College, Calcutta, the late R. F. Azo, and M. H. Husam, professor of Arabic at Presidency College. The principal object of the paper, which is provided with numerous references and notes of great value, and is illustrated, is confined to supporting the thesis that "in 900 AD. such a degree of exact knowledge of chemical substances and apparatus was displayed that historians may henceforward be justified in antedating the birth of scientific chemistry by—in all probability—at least 900 years, and, secondly, to indicating briefly the influences, both personal and racial, that appear to have controlled the development of chemistry in the period of investigation

There is nothing in the paper which would incline any one acquainted with the works of the Greek-writing practitioners of the 'Divine Art' at Alexandria, some 500 years before the period dealt with in the present memoir, to assent to the first part of the thesis, and it is much to be regretted that the enthusiasm of some writers on chemistry in Islam should often lead them to overstep the bounds of

reality.

The subject matter of the memoir falls naturally into two parts The first contains an account of the chemical information contained in two treatises written by Muhammad bin Zakarīyā ar-Rāzī, who is generally known (and will in what follows be called) by the name of Rhases (although this is really his address), and an encyclopædia of sciences written about A.D. 980 by Abū 'Abdallāh Muhammad bin Ahmad bın Yüsuf al-Kātib al-Khwārazmī, the Arabic text of which was published by Van Vloten in 1895; an English translation of the part of the latter dealing with alchemy is given.

Rhases was born in A.D. 866 at Ray, and was, like many other Arabic writing men of learning, a Persian. Rhases' treatises on alchemy are said by our present authors to be "scientific works in the modern sense of the word," and free from that "veil of mysticism with which even Jabir had continued to conceal from public view the mass of chemical facts that had gradually accumulated in the Near East up to the middle of the eighth century A.D." It may be useful to notice at this point that the writings of Jabir ibn Hayyan do, in fact, contain a good deal of childish mysticism, and that the claims put forward for his

'rationalism' are exaggerated.
One of the sources of Rhases' information, according to our present authors, was the "Book of the Seventy," a Latin translation of which in the Paris MS, Latin 7156 was mentioned by Hoefer in 1842 ("Histoire de la chimie," vol. 1, p. 409, 1842: "Liber de Septuaginta translatus a magistro Renaldo Cremonensi de lapide animali"—a treatise which, says Hoefer, "pourrait beaucoup intéresser les amateurs de la science hermétique. Il a été, selon toute apparence, traduit de l'arabe"). It was published by Berthelot in 1906, after he had suggested in 1893 that it was the work of the same title attributed to Jābir ıbn Hayyan in the "Kitab al Fihrist" of al Nadim. This has been confirmed, since the present memoir was written, by Julius Ruska, who has discovered the Arabic original. "The substances, apparatus, and processes mentioned by ar-Rāzī are, almost without exception, found in the 'Book of the Seventy.'" The authors proceed to demonstrate in detail the indebtedness of Rhases to Jābir ıbn Hayyan.

The second part of the memoir deals with the interpretation of the word Khārsīnī, which is mentioned as one of the metals in the treatise published by Van Vloten It is there said to be "a rare inetal, almost unprocurable" It is associated with the planet Mercury, and this leads the authors to a discussion of the planetary idols of the Sābians of Haiian, which are described in a treatise of Al-Dimish ( $\bar{q}$  (d A.D. 1327) translated by Chwolson, and also in full by Mehren "Manuel de la cosmographie du moyen âge," Copenhagen, 1874), in which the idol of Mercury "is made of an alloy of all the metals as well as of Khārşīnī, and in the hollow of which much quicksilver is poured " (Mehren translates Khārṣīnī as "Chmese porcelam," as does Chwolson). The literal meaning of Khārṣīnī is, according to the authors, "the Barb, or [poisonous] arrow-head of China"; it takes the place of glass in Jābir's list of the metals, and after an exhaustive examination of the other sources of information (in which they refer to "a further possible source of Arabic alchemy, viz., the Chinese School of Alchemy which was flourishing at least as early as B c. 200, and of which the chief exponent, Ko-Hung, wrote his treatise on Taoist Philosophy and Alchemy, called the *Pao p'o tsz'* in AD. 330"), they conclude that "the original Khārsīnī of ar Rāzī represented the metal now known to us as zinc."
They also refer to "the Chaldwan element in ar-Rāzī's chemistry, as indicated by the inclusion of Khārṣīnī in the list of metals," and suppose that "the ancient civilisation of Mesopotamia had still survived in his time at Harran" (a part of which comprised the Sabian planetary religion mentioned above), and that Chinese information was also available to him there. "Greek and Chinese alchemy must have had some common source of origin: and as the Chinese could hardly have drawn directly on Greek (or Egyptian) sources for this knowledge, China must either have discovered the facts for herself, and passed them on to some intermediary, like Babylonia, or acquired the knowledge from the same (or some other) intermediary. . . . In addition to the Greek knowledge of chemistry, which reached him through Jābir, ar-Rāzī also drew-in all probability through the Temple-priests of Harran in northern Mesopotamia—on the considerable body of knowledge at the disposal of the ancient Babylonian and Egyptian priests."

It is suggested that such information as that translated in R. C. Thompson's "Chemistry of the Ancient Assyrians" may have been transmitted directly, together with unspecified elements from other civilisations. This suggestion is clearly worth following up, since the usual opinion that chemistry is largely of Egyptian origin was put forward at a time when practically no information existed as to the technical knowledge of that people. Exaggerated claims for "a Babylonian origin of alchemy," such as those of Eisler, are still without confirmation, but the possible contributions from Mesopotamia grow more probable with fuller knowledge. In this connexion there is an interesting suggestion of Ruska (" smaragdina," p. 22) that the καιρικαί βαφαί of the Greek alchemical MSS. refers to the colorations of metals in the interior of the earth, which were formerly engendered by the action of the planetary spirits, but in the period when these actions had coased, could be effected by the 'divine art' of chemistry. This, in turn, seems to be related to the old Babyloniun belief in "spirits of mineral treasures" living under the earth, and related to the fire god.

The Chinese element assumed by our authors is

awaiting investigation, and it may be that Rhases' account of  $\underline{K}$ hārsīnī refers to mercury as a compound such as corrosive sublimate, which would correspond better with the Sabian account and with the poisonous properties of the material. I-Tsing (A.D. 671-695) seems to know corrosive sublimate, the production of which in China may have been early.

It has been possible only to mention one or two of the numerous interesting matters dealt with in the memoir, and the authors have performed a most useful and valuable service in its publication Students of this difficult period in the history of chemistry will await with keen interest the further memoirs which Principal Stapleton promises. J. R P.

# The Empire Mining and Metallurgical Congress.

THE first Empire Mining and Metallurgical Congress was held in 1924 at Wembley, on the occasion of the Butish Empire Exhibition, and the second will open at Montreal on Aug. 22 conferences are for the discussion of scientific, technical, and economic problems connected with the mineral industry, and they have in view the development of the mineral resources within the Empire They are arranged by an Empire Council consisting of delegates from five constituent institutions domiciled in Great Britain and five domiciled oversea.

The convening body for this second Conference is the Canadian Institute of Mining and Metallurgy. Invitations have been widely accepted from Great Britain, South Africa, Australia, and elsewhere within the Empire, while in addition many members of one or other of the institutions resident in the United States will attend. Probably, therefore, including ladies, there will be some 750 participants

The venue of the conference in Canada is a particularly happy one, not only because this year is the diamond jubilee of the Dominion's Confederation, but also because the mineral industry in Canada has risen so rapidly to a position of great importance that it may be regarded as being on the threshold of further

important developments.

The congress will begin by a session at Montreal on Aug. 22, and it will end by return to the same capital city on Sept. 28 Intermediate sessions will be held at Toronto and Winnipeg in succession, Intermediate sessions will the major portion of the conference then proceeding westward to Vancouver to visit Edmonton on the return, at both of which places there will be further sessions, while the remaining participants will turn eastward from Winnipeg to hold a session at Sydney in Nova Scotia. There will be, accordingly, full opportunity to visit all of Canada's important mineral fields from the Atlantic to the Pacific.

With the greatest sympathy, interest, and assistance from the Dominion and Provincial Governments. as well as from the Canadian mineral industry itself. the presentation of Canada's mineral resources to the visitors will undoubtedly be as complete as the best possible auspices can ensure.

The wider question of the Empire's mineral resources will be the feature of the discussions at the opening session at Montreal, when papers dealing with it will be presented, particularly from the Institution of Mining and Metallurgy, London So important, indeed, does that Institution consider the question to be that it has forwarded to the Conference the following resolution · "Resolved: That the Council of the Institution of Mining and Metallurgy being of opinion that the questions raised in the Paper submitted to the Institution by Sir Thomas Holland on a 'Proposed Review of the Mineral Resources of the Empire' are of vital importance to the British Empire as a whole, and to the Dommons, Dependencies, and Colonies, as units, think it desirable that they should receive serious consideration and discussion by competent authorities within the Empire.

Apart from this outstanding question, the Conference has been presented with an abundance of valuable papers from the other institutions and from prominent individuals, on the closer problems of the industry, scientific, technical, and economic. wherefrom all participants, whether from the homeland or from overseas, are assured of a lively and sustained interest in the proceedings. That interest, sustained interest in the proceedings the delightful tour, and not least the friendliness promised both in Canada and on the way there, constitute a sum of entertainment which explains the large number who have seen their way clear to

It is understood that the next of these Conferences will take place in South Africa in 1930.

## Mycorrhiza.

DR. M. C. RAYNER concludes her series of papers on mycorrhiza in the May issue of the New Phytologist. The final chapter is devoted to a consideration of the significance of these structures, and the nutrition of mycorrhiza plants. The author holds a brief for the view that the relationship between tungus and host plant is a reciprocal one beneficial to both symbionts, and implies an exchange of food material with a credit balance on the side of the vascular plant.

Evidence is adduced from experimental work on the relationship in forest trees, orchids, and heaths. In the case of conifers, the fungi concerned show marked stimulation in contact with the roots, due no doubt to the small quantity of exudates, particularly phosphatids, present. The infected root, on the other hand, seems to absorb morganic salts as well as, or in raw humus soils, better than, the uninfected roots. It is pointed out that the struggle for existence often centres about competition for suitable compounds of nitrogen, and the mycorrhiza habit enables the plant to draw efficiently on sources of nitrogen in the soil otherwise unavailable for its use.

On the other hand, there is no evidence that any of the known root fungi of trees can assimilate free nitrogen. While conifers can utilise ammonium compounds. more complex organic nitrogenous compounds are more readily utilised by the root fungi, and on acid humus soils, where such compounds constitute the chief source of nitrogen, plants with mycorrhiza are well equipped in competition with other forms. Orchid mycorrhizal fungı differ from those of conifers m retaining the power of autonomous existence. Seedling development is, however, conditional on infection. In the case of chlorophyllous forms, whether or not the mature plant can thrive in the absence of infection is an open question, but with non-chlorophyllous species, complete dependence on fungal symbionts is a condition of existence, as the food material of the plant must come from the humus in the soil.

The structural features of heath mycorrhiza

resemble those of conters more than of orchids. Calluna grows in human soil where there is a deficiency of mineral salts, particularly intrates, and mycorrhiza have been found most profusely developed in soils with abundant human, more sparsely in dry sandy situations, so it is possible that the beneficial effect upon the host may be directly related to soil conditions. Here again the mycorrhiza probably functions similarly to that of trees, enabling the plant to draw upon organic reserves in the humans.

In its evolutionary aspects the relationship now existing in orchids and heaths is considered to have originated in parasitism on the part of certain soil fungi. For this hypothesis it is necessary to assume that the invading strains were relatively mild in their action, and that the hosts had a relatively high resistance to parasitic attacks. Given this, it is easy to reconstruct the first stages of a symbiotic

association.

# University and Educational Intelligence.

CAMBRIDGE.—The John Winbolt Prize in engineering has been awarded to C Hinton, Trinity College, and W. R. D. Manning, Sidney Sussex College, for a joint dissertation on "Transverse Oscillation of Bridges"

SYDNEY.—Prof. R. S. Wallace, professor of English language and literature in the University of Melbourne, has been appointed vice-chancellor of the University of Sydney. He will succeed Sir Mungo MacCallum, who, at the special request of the Senate of the University, has consented to continue to discharge the duties of the office during the present year.

The following research scholarships at the Huddersfield Technical College are being offered by the Huddersfield Education Committee: A Drapers' Company's, in dyeing, value £100 with remission of fees; a Joseph Blamires, for research in colour chemistry, value £100 with remission of fees; and a British Dyes, for research in colour chemistry, value £75 with remission of fees. Particulars and forms of application are obtainable from the Technical College, Huddersfield.

In the seventh series of "Methods and Problems of Medical Education," recently issued by the Rockfeller Foundation, the School of Medicine and Dentistry of the University of Rochester, Rochester, N.Y., is described, with full details and plans of the buildings and many illustrations. The building embodies many novel features, and efficiency with economical construction has been the aim throughout. Corridors have been kept at a uniform width of 8 ft., and the distance from floor to floor is 11 ft. 2 in. Throughout all parts of the school the inner surface of the building walls are faced with an inexpensive grey 'sand-lime' brick, which reflects the proper amount of light for general laboratory work. Partition walls are constructed of 'sand-lime' brick of single thickness, strengthened by steel door frames anchored to floor and ceiling. No plaster has been used except in tollet rooms, all walls, columns, and ceilings are untouched by paint, and all pipes are exposed. The cost per cubic foot, including everything except equipment, is 39 cents for the school and 62 cents for the hospital, and equipment costs 4 cents for the school and just over 6 cents for the hospital, per

Prof. H. B. Fantham, professor of zoology in the University of the Witwatersrand, has published in the

South African Journal (vol. 23, p. 595) the address he delivered in 1926 at a joint meeting of Sections D and F of the South African Association for the Advancement of Science on the question of the teaching of animal biology in the Transvaal. In the course of the address he says, on the authority of Dr. Skaife, that in the Cape Province animal biology is now a compulsory subject in all the secondary and high schools. and that in 1925 no less than 2000 candidates took the subject in the junior certificate examination this respect the Transvaal apparently lags behind, and Prof. Fantham gives in his address reasons why biology should be taught in all the high schools throughout South Africa, and some practical suggestions as to the materials that might be used to illustrate the principles of the subject. In the Report of the British Association in 1921 a statement, drawn up by the Zoology Organisation Committee, was published on the teaching of natural history in the schools of Great Britain, in which similar reasons were given for the inclusion of the subject in all schools and a practical course was suggested. There has been some improvement since the date of the Edmburgh meeting, but education authorities in Great Britain are still far behind the Cape Province in their appreciation of the value of animal biology as a school subject. Prof Fantham's suggestions for courses on animal biology indicate the wealth of material there is in South Africa for teaching purposes and is of interest to zoologists, but the school authorities would probably be more impressed by a shorter and more concise proposal for a course of study. It is obvious that no school could ever cover the ground of his list of possible studies, and the head-masters will look to the professional zoologists for something more limited in scope that it would be practical to carry out in the limited time and equipment at their disposal.

RESEARCH in secondary education in the United States is held to be of such importance to the nation that a national committee has been formed for the purpose of promoting and guiding it. The Federal Bureau of Education, which is represented on the committee by its Commissioner, J. J. Tigert, and by E. E. Windes, who acts as secretary to the committee, has recently issued as Bulletin, 1926, No. 21, an outline, sponsored by the committee, of methods of research, intended for the guidance of school principals and teachers who wish to investigate some phase of secondary school work. The bulletin points out that helpful and indispensable as is laboratory research, its experiments are usually performed on selected groups under conditions which often simulate very imperfectly those of actual school life; likewise that much research can be carried out only in the classroom. Hence the importance of helping the school principal to develop in himself and his teachers an attitude of scientific research toward the problems that confront them and to acquire the requisite technique for conducting and reporting investigations. Chapters on the conditions essential to scientific research, the qualifications for the research worker, and types of research problems, are followed by a criticism of the questionnaire method of investigation in which wholesome warnings are given as to its many demerits. A useful outline of desirable procedure to be observed in reporting the investigation and its results follows, and there are a descriptive list of established research agencies and a bibliography of fifty recent publications. So many problems connected with secondary education in Great Britain require immediate attention to-day that this bulletin (Government Printing Office, Washington, D.C., 10 cents) should find readers among English secondary school principals.

# Calendar of Discovery and Invention.

August 15, 1869.—Imperishably associated with the name of de Lesseps, the construction of the Suez Canal was regarded as one of the greatest works undertaken. First suggested by de Lesseps in 1854, work was commenced in 1858, and on Aug. 15, 1869, the waters of the Mediterranean mingled with those of the Red Sea. When de Lesseps died, Engineering referred to the canal as being "far more truly the work of Lesseps than was the railway of Stephenson, the steam engine of Watt, and the spinning machine of Hargreaves."

August 16, 1822.—The discovery of thermoelectricity was first made known by Thomas Seebeck (1770–1831) on Aug. 16, 1822 Seebeck's early experiments were made with copper and antimony and

then extended to other pairs of metals.

August 16, 1814.—Brewster, while on a trip to Paris, recorded in his diary on Aug. 16, 1814, a visit to the Institute, where the business included a report by Poisson, a proposal by Legendre, and a long paper on iodine by Gay-Lussac. Of some of the famous men of science present he left interesting notes, describing Legendre as "a very tall and very thin man, with an expressive and intelligent countenance, white powdered hair, tied and curled above the ears"; Poisson as "a young and active little man, with a sweet and expressive countenance"; Delambre as "a little, oldish man, very yellow; a little marked with the small-pox"; Monge as "below the middle size, stoops, has a full face, and white curled hair"; and Lamarck as "a good-looking old man, with a light coat and an embroidered waistcoat, little and rather crooked."

August 17, 1807.—Fulton's famous Clermont—the first regular passenger steamboat in the world—made her trial trip on the Hudson on Monday, Aug. 17, 1807. Fulton's own statement ran: "I left New York on Monday at 1 o'clock and arrived at Clermont, the seat of Chancellor Livingston, at 1 o'clock on Tuesday; time 24 hours; distance 110 miles. On Wednesday I departed from the Chancellor's at 9 m the morning and arrived at Albany at 5 in the afternoon; distance 40 miles; time 8 hours; the sum of this is 150 miles in 32 hours—equal nearly 5

miles an hour."

August 18, 1854.—To Charles Bourseul (1829–1912), a French postal employee, we owe one of the first suggestions for a telephone. In an article in *Illustration*, Aug. 18, 1854, he suggested using vibrating plates to establish and interrupt connexion with an electric coil which acted sympathetically on a second

vibrating plate.

August 19, 1868.—During the total solar eclipse of Aug. 18, 1868, Janssen, "inspired by the beauty and brilliancy of the variously tinted prominence-lines revealed to him by his spectroscope, exclaimed to those about him, 'Je verrai ces lignes-là en dehors des éclipses.'" On the following morning he carried into execution the plan which formed itself in his mind while the phenomenon which suggested it was still before his eyes, and, says Miss Agnes Clerke, "During the whole of that day [i.e. Aug. 19], and many subsequent ones, he enjoyed, as he said, the advantage of a prolonged eclipse."

August 20, 1841.—In the study of physiological chemistry none did more important work than Liebig in Germany and Dumas and Boussingault in France. Liebig's report to the British Association on animal chemistry was made in 1842, while another important contribution was the lecture of Dumas and Boussingault, "Statique Chimique des Etres Organisés," delivered on Aug. 20, 1841. E. C. S.

## Societies and Academies.

#### LONDON.

Geological Society, June 15 —J E Richey: The structural relations of the Mourne granites (Ireland). The Mourne Mountains are some 13 miles long by about 5 miles wide, and include many peaks of more than 2000 feet in height. The granite-massif of inferred Tertiary age is intruded into Silurian shales, and truncates a north-westerly basic dyke-swarm The massif consists of at least four distinct intrusions, composed of different granite varieties. The Western Granite extends outwards on all sides below a slightly domed roof of shales, cappings of which rest upon the granite. The Eastern Granites are deeply eroded enough to show bounding walls as well as roofs. Floors are nowhere seen These Eastern Granites are arranged one within the other, with a marked excentricity towards one side. The outermost granite is the oldest, the innermost the youngest. Features observed by Traill are that granite-margins transgress the bedding of the Silurian shales, and that the direction of the dip of the shales is unaffected by the intrusion of the granites. The absence of xenoliths, except at actual margins, and the plane surfaces of contacts, are other noteworthy features. The spaces occupied by the various granites have been provided by subterranean cauldron-subsidence of the pre-The intrusion of the Eastern Granites existing rocks successively one within the other may be then explained by assuming renewed subsidence of the first-subsided block.—W. F. Whittard: The stratigraphy of the Valentian rocks of Shropshire: the main outcrop. It is the first of these that is described in this paper. The threefold classification of Salter and Aveline has been adopted, but their nomenclature has been modified: the rocks are subdivided as follows: (3) Purple shales; (2) Pentamerus beds; (1) Arenaceous beds. The Arenaceous beds extend from near Cardington north-eastwards to the Wrekin, and consist essentially of conglomerates, grits, and sandstones. Evidence is given for a southerly derivation of the pebbles comprising these beds, and Purple shales consist almost entirely of purple, maroon, or green mudstones or shales; shelly limestones and calcareous sandstones occur irrespective of horizon. The Valentian rocks are displaced by a series of dip-faults, but no folding, other than that caused by slip, has been detected. The Valentian rocks of the main outcrop seem to have been deposited in partly isolated or protected waters. The few graptolites so far obtained show that only Upper Valentian rocks are exposed.

### CAMBRIDGE.

Philosophical Society, July 25.—C. E Wynn-Williams A valve amplifier for ionisation currents. A method of using a valve for amplifying ionisation currents 100,000 times is described, which avoids the instabilities usually associated with such apparatus. Used in conjunction with a galvanometer of sensitivity 200 mm. per microampere, the system behaves in a similar manner to a low capacity quadrant electrometer of sensitivity 6350 mm. per volt, shunted by a leak of 360 megohms, the valve of the latter being slightly greater for negative currents than for positive.—C. F. Sharman A differential retarding potential method for the study of the energy distribution of slow electronic emissions. A discussion, given in a previous paper (*Proc. Camb. Phil. Soc.*, Pt. 5, vol. 23, p. 523), of the respective merits of the magnetic spectrum and of the ordinary retarding potential

method for the investigation of electron energy distributions is here elaborated, and the difficulties peculiar to the low energy region (from zero to 20 volts) are pointed out. Results of the application of the method to the secondary electrons excited in a copper surface by primary electron beams of energies from 200 volts to 800 volts are described —W. L. Webster The Hall effect in single crystals of iron. Experiments were made to determine whether the Hall effect varied with the direction in the crystal for which it was measured. The Hall potential was measured in four thin plates cut from single crystals, with quite different orientations For all of them, the Hall coefficient was the same within the limit of experimental error, having a value +0 97×10-2 -L H. Thomas The production of characteristic X-rays by electronic impact Two corrections are made to Rosseland's formula for the variation of the intensity of characteristic X-rays with the energy of the exciting electrons The velocity m its orbit of the electron knocked out of the atom and the increased velocity of the impinging electron are taken into account. The formulæ are compared with Wooten's experimental results for the  $K_a$  line of molybdenum.—F. P. White: Simplexes and other configurations upon a rational normal curve—R. W. Ditchburn: Notes on spectro-photometry

dimorphism of this species is confirmed. The toxic effect of copper sulphate is different on the two sexes -A Borloz. A critical study of the methods of analysis of antipyrin and pyramidon. After an examination of the known methods, the author recommends for the analysis of a mixture of these two substances the method of Péguner-Lemaire, but avoiding the neutralisation by hydrochloric acid and methyl orange before the precipitation with pierie acid.—E Briner and Ch. Boissonnas: The energy yield of the formation of ozone by the silent the charge. In laboratory researches, the power absorbed in the ozoniser has been too often confused with the product of the voltage by the current. The true yields are up to ten times greater than those intheito calculated, and their relations with the pressure are different -L. A. Deshusses. A correction of the Avery-Beans method (the estimation of arsenic in Schweinfurth green). The comparison of the results of this method with those of the gravimetric method or by distillation of arsenic trichloride in the presence of methyl alcohol has proved that the Avery-Beans method has a systematic plus error -P. Wenger and M. Gysin. The estimation of carbon dioxide in lunestones. limestone is attacked by a boiling solution of sulphuric day from the carbon doxide is fixed by caustic potash. Unlike hydrochloric acid, the sulphune acid is not carried over into the potash tube because its vapour pressure is

#### SYDNEY.

Royal Society of New South Wales, May 4.-W. G. Woolnough (Presidential address). The general chemical principles involved in the weathering of rocks during the last stages of highly perfect peneplanation are discussed, and it is shown that, if the rainfall of the region is markedly seasonal in distribution, the conditions tayour the production of: (1) A very deep zone of completely leached rock, consisting essentially of kaolin and silica, (2) a sub-surface deposit typically concretionary in structure of amorphous silica, alumina, and iron oxide. All the alkalis and alkaline earths are completely removed in solution. An attempt is made to prove that the very widespread 'lateritic' and siliceous crusts so ubiquitous over western and northern Australia, are parts of a single chemically-formed deposit, produced under the conditions postulated in the first part. Such crusts have been referred to a number of different geological formations, and endless confusion has resulted. It is believed that 'Desert Sandstone,' 'Laterite,' 'Upland Miocene,' and other formations in different States may be brought into harmony with one another. For the formation thus produced the name of 'Duricrust' is suggested. Reasons are adduced for assigning the Miocene age to the structure. The Duricrust economic importance as it yields precious opal, fireclays, road metals, water supplies in and regions, and possibly bauxites of economic value. Its surface is mostly extremely barren, and its destruction has given rise to the great stony plains (gibber plains) so widely developed in the interior of the continent. Remnants of it give rise to the 'tent hills' and 'table hills' so characteristic of Central Australia

# Safety in Mines.1

T is satisfactory to note from the Fifth Annual Report of the Safety in Mines Research Board, just issued, that researches of an important character are being actively pursued, and especially that the Board appears to be taking a wider view of its duties than was at one time the case. It has been pointed out more than once that the tendency of the Research Board was to trust too implicitly to laboratory investigations, and that as an almost necessary consequence many of the researches were confined to chemical or physicochemical problems. What is particularly needed to-day is investigation of mechanical problems. These are of such a nature that their proper investigation can be carried out only in the pit, and laboratory work can do little more than give an indication of the direction in which the researches would need to be prosecuted.

The most fertile cause of underground accidents is still, as it has been for many years, that occasioned by falls of ground, an investigation, sufficiently complete and searching to enable suitable remedies to be suggested, is necessarily a lengthy and wearisome one, and one which can only be carried out underground. It is, therefore, gratifying to observe that investigations of this type are being actively pursued. The results obtained by the dynamometer-prop, the object of which is to measure the actual roof pressures experienced in the mine, will be looked forward to with great interest, though every experienced mmer knows that it is not the amount of pressure only which matters; a roof which weighs heavily, but can be so controlled as to take advantage of that very weighting for the purposes of coal getting, is likely to be a source of much less danger than the roof which presses less heavily, but is apt to break up without warning.

Among the reports of results of investigations issued during the course of the year was an exceedingly valuable one on the East Midland Coalfield, in which the results obtained by steel props were recorded and their more general adoption, at any rate on an experimental scale, was advocated. Such props are attracting considerable attention, and it is to be hoped that the Safety in Mines Research Board will continue to investigate the respective advantages and drawbacks of the different types of props which are being put on

<sup>&</sup>lt;sup>1</sup> Mines Department. Fifth Annual Report of the Safety in Mines Research Board, including a Report of Matters dealt with by the Health Advisory Committee, 1926. Pp. 55. (London: H.M. Stationery Office.) 9d. net

the market. It may be noted that the Board has had tests carried out on quartered props, which show that these props are as strong as round props of the same sectional area. It may be doubted whether it was worth while carrying out these tests, seeing that the subject has been fully dealt with in Germany, and the German reports show exactly the same conclusion as has been reached in Great Britain (see Gluckauf, 1926, p 1409). It is, however, some satisfaction to find that the results which have been obtained by the British and German investigators have led to identical conclusions.

Another subject on which the Safety in Mines Research Board is initiating an investigation, is wire ropes, and this may be described as an investigation of first-rate importance. It is true that colliery accidents due to the failure of wire ropes are exceedingly rare, and that they stand almost at the opposite end of the scale to that which accidents from falls of ground occupy. Nevertheless, it may fairly be said that there is no article in common everyday use about which our ignorance is so profound as is the case with the wire rope, and any information concerning wire ropes will be eagerly welcomed. No fault can be found with the objects of the wire rope committee, namely, to discover means of prolonging the life of the rope and of foretelling probabilities of failure: but the method which the committee proposes to adopt, namely, to examine samples cut off from the ends of winding ropes when re-capping takes place, is decidedly open to objection.

Whilst it is a fact that winding ropes very rarely fail at the cappings, it is nevertheless certain that the end of the rope where it enters the capping is liable to much more severe corrosion than any other part of the rope; where ropes are capped by running in white metal, local galvanic action may be expected, and, in any event, this is the point at which acid water, however produced, is most liable to accumulate. On the other hand, the end of the rope is never exposed to bending stresses, which affect every other portion of the rope as it passes over the pit-head pulleys and round the winding drum. These stresses, with the consequent alternation of stress, are bound to have a more or less injurious effect upon the rope, and this effect will be entirely missed by investigations confined to the end of the winding rope. There is no doubt that winding and haulage ropes constitute a vast field for investigation, and it is highly satisfactory to learn that a systematic

attack upon these problems has now been commenced.

Among other researches of importance is one upon the improvement of the lighting efficiency of safety lamps, both electric and flame lamps. and the report certainly suggests that a very considerable measure of success has already been attained. The publication of the full account of this work will be looked forward to with much interest. Researches upon coal dust and firedamn explosions and upon mining explosives are, of course, being steadily continued. Naturally, this aspect of the work is very closely connected with operations at the Buxton Research Station, the official opening of which took place only a few weeks ago. There is no doubt that the geographical position of this station is an immense improvement upon Eskmeals, and the experience gained by the latter station will no doubt have been fully utilised in the design of the new station. so that this may be fully equal to all the work required of it, both as a testing station and as a research station.

Important results may be expected from the electrical researches in progress, the ultimate object of which is to obtain electrical appliances which shall be absolutely safe for use in underground work even in fiery pits. Other subjects which are briefly dealt with in this report are researches on the spontaneous combustion of coal and the investigation of certain defects in mine rescue apparatus, which have been found in practice to cause inconvenience: the report indicates that remedies for these defects will in all probability be forthcoming as the result of these researches. There is a brief reference to the constitution and the work done by the Health Advisory Committee, which has now been brought into closer relationship with the Safety in Mines Research Board by the appointment of Sir Edward Troup as chairman of both.

The report contains two interesting appendices, one being a programme of the researches of the Board which are either in progress or under consideration, and the second a report on the co-operative researches that are being carried on jointly by the United States Bureau of Mines and the Safety in Mines Research Board. It is sincerely to be hoped that this scheme of co-operation will be further extended until it embraces all the researches carried on in all the coal-mining countries of the world upon objects identical with those of the British Safety in Mines Research Board.

# Forestry in India.

The Forests of India By Prof. E. P. Stebbing. In 3 vols. Vol. 3: The Progress of Conservancy and the Development of Research in Forestry, 1901–1925; including Brief Reviews of the Progress of Conservancy in the several Presidencies and Provinces between 1871–1900. Pp. xix+705–122 plates. (London John Lane, The Bodley Head, Ltd., 1926) 42s. net.

THE third and final volume of "The Forests of India" is divided into two parts, the first of which deals with the period 1871–1900. and contains brief descriptions of the main features which affected progress in forestry in the different provinces. The period covered by this section of the book corresponds more or less to a definite stage in the development of Indian forestry. It is the period of reservation and demarcation of an area to be permanently maintained under forest

In reading Part 1 of this volume it is important to realise that India is not homogeneous. Apart from differences in geographical, topographical, and climatic conditions, which result in different forest types and therefore different forest values, the provinces themselves were in varying stages of development and had different histories. Different forms of land tenure existed, and the people differed in local customs and methods of cultivation. Prof Stebbing devotes a separate chapter to each province and gives us an outline of the difficulties to be overcome.

In all countries the history of progress in forestry is the history of the education of the people, and in India a second factor existed, the need for educating the civil authorities. All through we find instances where the latter were antagonistic, or at least unsympathetic, to the Forest Department, and although this may appear to be an unusual feature, it has its explanation in what is described as "a supersensitiveness on the part of the civil authorities on the question of the rights of property" and their reluctance to interfere unnecessarily with local customs. Examples are quoted where this attitude was undoubtedly carried to extremes; but considering the past history of India, this feature was largely unavoidable and its delaying effect may not have been unduly great.

The factors which were primarily responsible for progress were economics, and examples are to be found in most provinces. The visible effects of the destruction of forests on the water supply and erosion, the increasing demand for and the diminishing supply of cheap fuel and timber, were

the things which finally convinced local governments of the need for defining a policy with reference to forest areas.

During the thirty years under review, India was fortunate in having at its disposal the services of three very able Inspectors - General, Brandis, Schlich, and Ribbentrop Prof. Stebbing quotes largely from the reports of these officers, particularly those of Brandis, whose energy and driving powers were amazing.

It is impossible to deal with all the aspects of the developments which are mentioned in Prof. Stebbing's book; but perhaps the most striking fact is the dependence of progress on the close cooperation between the Chief Forest Officer and the local government on one hand, and on the maintenance of friendly relations between the Divisional Forest Officer and the local inhabitants on the other. Where these two conditions exist, the progress of education goes on smoothly and with the least delay.

In other branches of forestry developments were also taking place. In Burma, the United Provinces, and the hill divisions of the Punjab, forests were being worked under regular 'working plans,' and in Ajmer-Merwara and the plains of the Punjab we find the first attempts to re-afforest areas, where the destruction of forests had proceeded too far.

By the end of the last century the progress was such that the area under forest compared favourably with that in other countries in Europe and elsewhere, the general lines of forest policy had been definitely laid down in all provinces, and the forest service was firmly established. Part 1 of this volume is a striking tribute to the first three Inspectors-General.

In Part 2, Prof Stebbing deals with developments between 1901 and 1925, and in the opening chapter he gives a short review on the administration of India during this period. In the following chapter, which is devoted to forest administration, he points out how sylviculture, working plans, utilisation, and research now take precedence over reservation, protection, and forest legislation. On p. 262, while acknowledging the debt owed to the first three German Inspectors-General, he would have us believe that the very rapid progress in recent years dates from the change to English Inspectors-General and, in particular, from the inauguration of the Imperial Research Institute in 1906. If this is to imply that the formation of a research branch is the cause of the rapid development, this is an opinion which will not be accepted by many

forest officers in India, and it is preferable to continue to look upon the progress made as a natural evolution governed by economic factors, such as the growth of Indian industries and the stimulus of the War.

252

The figures on p 622 in the chapter on yield and revenue for imports of railway sleepers, which increased in value from less than Rs30,000 in 1919 to nearly Rs40,00,000 in 1923, speak for themselves. The sanction of the large sum of money for the new Research Institute was feasible only on account of the economic need for expansion in research, particularly in the branch of forest economy. We find the same rap d advance in other branches, sylviculture, working plans, and utilisation, the splitting-up of territorial charges and increases in staff, due not to forest research but to the forests becoming economically more important to India.

The chapter on forest research is of particular interest and well illustrated by photographs, which give some idea of the scale on which the new Research Institute is equipped. The author also deals with advances in sylviculture, afforestation, fire-protection, working plans, and exploitation, and in Chap. xiii. discusses forest education and the training of probationers for the Indian Forest Services. In this chapter he expresses opinions which will not find favour with all, particularly on the subject of "training under subsidised German Forest Officers" and on the value of tours on the continent of Europe.

On the question of Indianisation and the future training of Indian probationers, now 75 per cent. of the annual recruitment at Dehra Dun, Prof. Stebbing appears pessimistic In Chapter xvi., on sylviculture, he admits that "at the present day work on as high a plane as anything on the continent of Europe is to be seen in India." He proceeds to qualify this statement by "the proviso that these methods have been so far only applied to a comparatively small area," and gives it as his opinion that "India is not yet in a position to afford as valuable a training ground as exists in Europe, because with few exceptions no Indian forest has yet passed through a whole rotation" Some of those who have had experience in teaching forestry at Dehra Dun and have also re-visited continental forests, will be inclined to think that Prof. Stebbing has been too emphatic on this point. Whatever views are, however, held on this point, it is now the accepted policy of Government to train three-quarters of the future probationers in India, to be followed by a visit to the continent

after three years in a division, and, as is pointed out, it rests with those responsible for the selection of the right type of probationer and for the control of the new training centre, whether the future is to be retrogressive or otherwise.

Prof. Stebbing's book contains a vast amount of information on all aspects of Indian forestry and is essentially a historical record of a department of which India may justly feel proud. It is as a history rather than as a critical work that the book is of value.

Little need be said on the arrangement of the book or the subject matter The author has had to deal with a large subject, covering a period of time during which conditions were changing very rapidly. He must have experienced considerable difficulty in selecting from the mass of official reports and papers those which could most suitably be included to illustrate half a century of forest progress.

Prof. Stebbing is to be congratulated on having compiled a history, which gives so many concrete facts about one of the departments the activities of which are carried on far from the public eye, and on the excellent photographs with which the book is illustrated. In his preface the author expresses the hope that he has been able to show that the Indian Service can take rank with some of the most organised forest services in Europe, and those who read his book will agree that he has achieved his object.

C. E. Simmons.

## Band Spectra.

Bulletin of the National Research Council. Vol. 11, Part 3. No. 57: Molecular Spectra in Gases. Report of the Committee on Radiation in Gases Pp. 358. (Washington, D.C: National Academy of Sciences, 1926.) 4 dollars.

ONE of the most formidable obstacles to the progress of science at the present day is the manner in which it is progressing. The continuous increase in the number of research workers and in the scope of their investigations cannot be a source of unalloyed satisfaction to the carnest seeker after knowledge, who before ever he begins a research must delve long and laboriously in the files of countless periodicals in order to discover just where he should begin. There are abstracts, it is true, but they are seldom adequate; in practice one finds them chiefly useful in facilitating reference to the papers really relevant to one's purpose. From this point of view they are often extremely valuable, but from time to time in the develop-

ment of a subject the need becomes urgent of a pause to review the results obtained and to consolidate the advances made. It is a difficult task, demanding much labour, critical judgment, and breadth of vision. A mere compilation is not enough, for in the study and co-ordination of so many researches numerous problems are bound to arise which call for immediate investigation with the object of removing discrepancies or establishing generalisations Yet the compiler must exercise a nice discrimination in embarking on such researches, for publication cannot be long delayed if the work is to be up-to-date and not unduly littered with "notes added in proof." Obviously, then, it is not a task to be undertaken lightly, but on the other hand, if well done, it should be of mestimable value, not only to the worker in the particular region surveyed but also to those in neighbouring fields as well

The time was undoubtedly ripe for such a review of band spectra In the last ten years a rich harvest of results has been reaped, but scarcely garnered, and the phenomena in question are of such a complex character that no survey could be adequate unless planned on a rather considerable scale. For this reason the National Research Council did wisely in entrusting the task to a committee rather than to an individual. In the pre-- sent case the consequent loss of homogeneity is certainly outweighed by the gain in authoritativeness. There are five contributors · two of them (Kemble and Page) deal with the theoretical side of the subject, and the other three (Colby, Birge, and Loomis) mainly with the experimental, under the headings of infra-red absorption bands, electronic bands, the isotope effect, and fluorescent band spectra.

The second of these sections is by far the largest, comprising in fact more than half the book. This is natural enough, since bands of the electronic type (i e. involving changes of electron configuration) are both the most complex in structure and the most accessible to investigation. Prof. Birge's task must have been an exceedingly difficult one, particularly in view of the rapid progress which has recently been made in the interpretation of optical bands, but he would probably be far from regretting the undertaking, for the researches which presented themselves in the course of the work have had some notable results. For example, they led him to the recognition of the essential similarity between molecular and atomic electron transitions, a conclusion of great importance and Congratulations are due to him upon fruitfulness an extremely valuable piece of work.

The other sections also contain much that is interesting and suggestive. In the account of infra-red absorption bands (Colby) one would have been grateful for a little more information concerning the far infra-red region, so full of difficulty and promise. The section on fluorescent band spectra (Loomis) deals actually with that of iodine only, but the facts described are certainly of sufficient interest to justify the allocation of a whole chapter to them. It seems to the writer that the discussion here is not quite so easily followed as could be wished, but this may be a merely personal difficulty. Chapter v., also by Loomis, is a very useful account of the isotope effects occurring in band spectra. Up to the present these observations have served mainly to confirm band spectrum theory, the isotopic constitution of the elements being already well established, but it is not improbable that they may find wider applications in the future.

The final chapter, by Prof. Kemble, is a masterly survey of certain theoretical aspects of the subject. The account of Hund's recent work on bands will be found particularly valuable, and the section on the Zeeman effect also calls for special mention, providing as it does a basis for discussion and extension of the rather perplexing results already obtained in this connexion

One of the most valuable features of the Report is the systematic notation scheme which has been used throughout. Progress would be greatly facilitated if this were universally adopted by writers on the subject. The volume is admirably produced, and misprints are very few. There is a reference to the "first measurement" of the MgH band  $\lambda5211$  as by Watson and Rudnick (mstead of by Fowler), but this may be nothing more than a slight ambiguity of construction The bibliography, whilst professedly incomplete, is very extensive, but it is a great pity that no index is provided.

## Sex Physiology for the Laity.

Sex in Man and Animals. By John R. Baker.
Pp. xv1 + 175 + 4 plates. (London: George Routledge and Sons, Ltd., 1926.) 7s. 6d. net.

THE need for an inexpensive book on sex addressed to the interested layman and written by a trained biologist has long been recognised. It is true that there are many popular books dealing with this subject, written during recent years by sincere enthusiasts whose chief claim to authorship would appear to be an irresistible yearning to help their fellow-women;

but the extent of the ignorance of established biological fact and the easy disregard of scientific method exhibited by these authors have forced the professional and responsible biologist to accept the task of democratising the knowledge that he possesses. Biology, and especially sex-physiology, is the field in which any and every one exercises his or her opinions. The chemist or physicist can speak of his science without interruption, for in it there still is magic, but let the sex-physiologist speak and his voice is at once drowned in violent controversy. Impressionistic, anecdotal, uncritical doctrine, born of desire and supported by insufficient and inexact observation, denies the logical inferences of dispassionate experimentation, and the people, eager for information and for guidance, are led along the road that leads to disappointment and disillusionment, while the eyes of many still remain blinded by hope.

To the general public sex is still, in spite of the abundant fruits of the last five-and-twenty years of most profitable research, one of the great mysteries. It is high time that the layman should be told that, though as yet all concerning the details of the processes of sex-determination and sex-differentiation is not known, it is the case that the salient and significant features of these processes are already apprehended. The study of the chromosomes and of the internal secretions has revealed the precision and the wonder of the mechanisms concerned, and the advance in knowledge concerning sex has been such that already it is possible to control the expression of certain of its aspects. It is desirable that this knowledge should be placed before the public, whose lives are continually affected in one way or another by one or more of the various manifestations of sexuality; it is desirable that there should be made available a fair statement of current scientific opinion concerning sex; it was high time that some professional biologist, well equipped for the task and with a flair for interpreting scientific terminology into language readily understood by the man in the street and the woman in the home, should place his services at the disposal of those who desire to learn.

Mr. J. R. Baker, provoked by the manifest need for such an exposition, has discussed the facts adequately, frankly, and rationally. In his book, addressed to students of biology and of medicine, the subject matter is well chosen and well arranged and the language is simple. It is written especially for those who look to others for their creed. Among the well-sustained conclusions of many

authorities are dispersed the personal opinions of the author concerning not only the biological but also the anthropological, psychological, and sociological aspects of his subject, and it is not always easy to distinguish between generally accepted facts and reasonable but personal point of view concerning the possible implication of these facts in relation to human affairs The author writes with courage and with competence as one willing to accept the responsibilities of leadership and as one who sees the goal of human endeavour. In his praiseworthy attempt to democratise scientific knowledge he has deliberately avoided meticulous accuracy and any profound consideration of elaborate detail, and so the real significance of the general principles of the subject is not obscured.

Since his teaching cannot be reconciled with the preferences and prejudices of the multitude who dedicate their activities to the dissemination of their own speculative but attractive theories and methods of controlling sex, the author must not expect that his teaching will be as widely followed as it deserves to be. He has, however, the satisfaction of having written a book that must be of great value to any one who, being eager to hear of what is known and of what is reasonable, seeks to sit at the feet of somebody who himself has contributed quite notably to our knowledge of sex

## A Contribution of Science to Religion.

Religion in the Making: Lowell Lectures, 1926.

By Prof. Alfred North Whitehead. Pp. 160.

(Cambridge: At the University Press, 1926).

6s. net.

In the preface to this volume the author refers to the four lectures on religion delivered in King's Chapel, Boston, during February 1926, in which the train of thought which was applied to science in his Lowell Lectures of the previous year ("Science and the Modern World") is here applied to religion. It is stimulating to read this book from the pen of one who can speak with such authority and experience in the realms of mathematics, science, and philosophy.

The work is divided into four chapters, the first of which, "Religion in History," begins with the definition of religion: the theme developed is that religion is solitariness.

"Collective enthusiasms, revivals, institutions, churches, rituals, bibles, codes of behaviour, are the trappings of religion, its passing forms. They may be useful, or harmful; they may be authorita-

tively ordained, or merely temporary expedients. But he end of religion is beyond all this. . . . What should emerge from religion is individual worth of character ''

The emergence of religion is traced and four factors are exhibited—ritual, emotion, belief, rationalisation. The bible is by far the most complete account of the coming of rationalism into religion," and the effect of travelling and trading facilities eventually produce a world-consciousness. The same growth can in essence be traced in India and China. In the last section of this chapter rational religion is described as the wider conscious reaction of men to the universe in which they find themselves. Generality is the salt of religion.

The dogmas of such religions as Christianity and Buddhism, especially with regard to the problem of evil, form the subject of the second chapter, "Religion and Dogma" The contrast is seen in Buddhism as a metaphysic generating a religion, whereas Christianity has always been a religion seeking a metaphysic The life of Christ is not an exhibition of overruling power, its glory is for those who can discern it and not for the world. Its power hes in its absence of force It has the decisiveness of a supreme ideal, and that is why the history of the world divides at this point of time. There are three concepts on which religion is founded, namely, that of the value of an individual for itself, that of the value of the diverse individuals of the world for each other, and lastly, that of the value of the objective world. To the query of value and the attainment of light, comes the answer that religion is world-loyalty. In the greatest of all religious dogmas—What do you mean by 'God' 2—there are three simple renderings of this concept. the first that of the eastern Asiatic concept of an impersonal order, and then the Semitic concept of a definite personal entity, and lastly the pantheistic concept. If the modern world is to find God, it must find Him through love and not through fear; the author emphasises the help of St. John in this direction, rather than the God of vengeance.

The third chapter is metaphysical and leads up to God and the moral order: value and the purpose of God, body, and mind. The fact of the instability of evil is the moral order in the world. The order of the world is no accident; value, beauty, zest of life, peace of life, and the mastery of evil are all bound together, and the religious insight is the grasp of this truth in relation to the completed ideal of harmony, which is God.

Finally, Prof. Whitehead investigates the applica-

tion to religion of a contrast between 'dogmatic' and 'empiric' Again, the divergence of the two traditions of Buddhism and Christianity is traced. with a reference to absolute idealism as a reaction for Buddhist metaphysics on the part of Western Meanwhile science had appeared as a third organised system of thought, and both Christianity and Buddhism, having unduly sheltered themselves from each other, were unable to reveal the requisite flexibility of adaptation Such men as demanded by the rise of science Origen and Erasmus in the Christian Church have, at any rate, recognised the central importance of this adaptability The book closes with references to the nature of God as the complete conceptual realisation of the realm of ideal forms. kingdom of heaven is God God in the world is the perpetual vision of the road which leads to the deeper realities, God upon Whose wisdom all forms of order depend

It is certainly to be hoped that Prof White-head's work will be carefully studied by all who mould current theological opinion H. D. A.

## Our Bookshelf.

Metallurgy of Cast Iron: a Complete Treatise for Engineers, Foundrymen, and Students. By J. E. Hurst. (The Specialists' Series) Pp. xvi+311. (London: Sir Isaac Pitman and Sons, Ltd, 1926) 15s net.

Cast iron has a very limited literature in comparison with steel, and it is only lately that any considerable attention has been given to its scientific study, although isolated workers have attempted from time to time to elucidate its complex problems. The author of this little book has an extensive practical experience of the subject, and has been responsible for several improvements in technical practice. He therefore speaks with authority on matters concerning the foundry. Cupola and moulding practice are not dealt with, and the book is devoted to the chemical and physical characteristics of cast iron in their relation to its use in the foundry. The chemistry is not always correct, but the errors will not mislead the practical reader to any serious extent. The vexed question of the relations between sulphur and manganese deserves more detailed consideration than it receives here, but it is a point on which an author scarcely dares to be dogmatic.

In view of the author's personal experience, it is surprising that so little is said of casting in permanent moulds, especially by the centrifugal process, whilst one also misses a discussion of the various methods now adopted, mainly on the suggestion of German inventors, for obtaining strong and tough irons by heating the mould or by using high casting temperatures, after controlling the chemical composition according to definite

rules Maurer's diagram is open to objection because it does not take into account the varying thickness of castings, but it is a useful guide, and can be modified to give graphical methods of calculating compositions which have proved to be of real use in the foundry, so that it should have been mentioned. The statement concerning viscosity on p 275 is incorrect, and is based on a misunderstanding. The work of Wimmer on the viscosity of molten cast iron was perhaps published too late for inclusion.

C. H. D.

Die Massanalyse Von Dr. J. M. Kolthoff. Unter Mitwirkung von Dr. H. Menzel. Erster Teil: Die theoretischen Grundlagen der Massanalyse. Pp. xii + 254. (Berlm: Julius Springer, 1927.) 10 50 gold marks.

Dr. Kolthoff, of Utrecht, has undertaken in an able manner the task of producing a readable volume dealing with the fundamental principles of volumetric analysis from the point of view of the ionic hypothesis and the law of mass action justification of such a work is that by the application of these principles new methods of analysis may sometimes be deduced by direct rather than by empirical reasoning This is particularly true of reactions involving neutralisation, precipitation, and the formation of complex ions, with which the first part of the book deals. Oxidation processes, on the other hand, are more elusive, since the range of indicators which will detect a definite oxidation - potential is at present somewhat restricted. Attention is directed to the promising results, published by W. M. Clark and others in the U.S. Public Health Reports, on the use of indigosulphonic acids and indophenols. In many cases, however, the disturbing influence of catalysts or of induced by-reactions has to be taken into account

Special attention is also devoted to the theory of indicators, to titration errors and to adsorption phenomena, and a chapter deals with the application of volumetric analysis to organic chemistry. The author is mainly concerned with titrations requiring indicators, but potentiometric methods are briefly described in the last chapter. Tables of useful constants form an appendix and there are numerous references to modern literature in the foot-notes. The German text has been produced in collaboration with Dr. Menzel, and a later volume on the practical application of the methods is promised

Kings of the Hittites By Dr. D. G. Hogarth (The British Academy: The Schweich Lectures, 1924.) Pp. viii + 67. (London: Oxford University Press, 1926.) 6s. net.

Dr. Hogarth has published his Schweich Lectures for 1924 practically in the form in which they were delivered before the British Academy, his reason being that owing to the still imperfectly published state of the results of excavation, the time has not yet come for fuller treatment. In this he has been wise, for, well argued as are his conclusions, his method of treatment in lecture form serves to emphasise their still extremely tentative character.

His kings of the Hittites are those of the Biblical narrative, the rulers of the southern Hittites, to whom reference occurs in the Chronicles of the historic age as holders of States to the north of Palestine in the earlier period of the Jewish monarchy. His purpose has been to illustrate their civilisation and to try to discover their origin and racial character

The evidence upon which Dr Hogarth draws is that imperfectly published, as already stated, from the sites of Zenjirli, Sakjegeuzi, and ('archemish. In discussing the connexion with the Cappadocian Hittite, Dr Hogarth is inclined to see a common origin rather than a direct connexion For this origin he suggests we should look towards the east at the early part of the second millennium B.C. with a leaning towards its identification with the Mitanni. Dr Hogarth by no means minimises our lack of knowledge of this people, and his readers will tully agree as to the need for exploration of the northern area of Mesopotamia, in which their influence was dominant, before we are likely to deal with any approach to finality in this and the other problems which he discusses.

La technique photographique Par L-P Clerc. Préface de Ch. Fabry. In 2 vols. Tome 1. Pp xx+458+2 planches (Paris Paul Montel, 1926) 100 francs les deux vols.

During the last decade or two there have been notable additions to our knowledge of the fundamental facts upon which the practice of photography depends, and some of the problems of twenty years ago have been at least partly solved. Added to this, new needs have arisen, and these have led to the production of new apparatus and new methods of working. It follows that for some few years the want of a modern text-book has been acutely felt by students and their teachers, and it is exactly this want that has been met by M. Clerc We hope that it will not be very long before a similar text-book is produced in English. M. Clerc knows well, from his experience as a teacher, what the student of photography needs, and he has used his knowledge of this and of the subject with great discretion. He has not neglected old facts to make room for new, or so shortly summarised the new as to make the references to them unintelligible. The illustrations are good and well chosen—not from manufacturers' catalogues. The subjects dealt with in the first volume are light and vision, and the apparatus, materials, and processes used in making negatives, leaving the consideration of printing methods for the second volume.

Reptiles and Amphibians their Habits and Adaptations. By Thomas Barbour Pp. xx+125+52 plates. (London: George G. Harrap and Co, Ltd, nd) 10s 6d. net.

This is one of the few books dealing with a neglected branch of natural history, and, though it aims chiefly at interesting a wider public in these much misunderstood animals and is consequently rather of the 'semi-popular' type, it will form a welcome addition to the library of the more serious student. As its author candidly admits, the book lacks contimuity, but gives a very readable, though necessarily incomplete, account of the principal morphological, physiological, and habitudinal modifications which the recent reptiles and amphibians have undergone The whole work is profusely illustrated and, though errors are not entirely absent, the text is essentially sound; one can only therefore regret the occurrence of such a sentence as this: "——and marvellous developments have been attained, though by infinitely slow degrees, to enable these fascinating creatures [snakes] the better to fit into the environmental niche pointed out to each plastic form by the inevitable finger of evolution. It would be interesting to know whether Dr. Barbour really believes that the evolutionary changes an animal has undergone determine the environment it occupies. There is no index

 $\begin{array}{cccc} \textit{Feuchtigkeitsmessung.} & \text{Von Dr} & \text{Hermann Bongards} & \text{Pp. vii} + 322 + 2 \text{ Tafeln} & (\text{Munchen und Berlin}: R Oldenbourg, 1926.)} & 17 \text{ gold marks.} \end{array}$ 

The measurement of the humidity of the air as effected both at an ordinary climatic station and by sounding balloons is not very satisfactory, different methods of estimating evaporation also give different results. So this systematic account of the various processes of measurement that have been developed is of real value not only in a meteorological department, but also to such commercial enterprises as control the quantity of moisture in the air of their factories

After a lucid statement of the physics of gases and vapours, Dr. Bongards groups the processes of measuring humidity according as they are dependent on (a) absorption, (b) saturation, (c) partial condensation of the water vapour, (d) evaporation, and (e) the hygroscopic properties of bodies, he also briefly describes the effect of water vapour on the optical, electrical, and other physical properties of bodies. The comprehensive nature of the treatment may be inferred from the fact that there are 126 diagrams or illustrations of instruments, where advisable their theory is fully discussed and practical advice in their handling is offered. The necessary tables are provided, and full indexes make the volume easy of reference

Permanent Consultative Committee on Official Statistics Guide to Current Official Statistics of the United Kingdom: being a Systematic Survey of the Statistics appearing in all Official Publications issued in 1926 and in certain Selected Publications issued in 1927. Vol 5 (1926) Pp. 273. (London: H. M. Stationery Office, 1927.) 1s. net

THE charge can no longer be made against Government departments that official statistics are hidden in departmental publications of which only the initiated are aware. This valuable volume, issued at a nominal price, is a complete guide to all official statistics published during the past year. It consists of two parts, a subject index and a list of publications arranged under the headings of the departments of issue. The subject index is full and well supplied with cross references. No

worker in need of Government statistics should have any difficulty in tracing what is available by the help of this volume. It is a work of reference which deserves a wide circulation

Données numériques de biologie et de physiologie et chimie végétales Rédigées par Prof. E F. Terroine et par Prof. H Colin (Tables annuelles de constantes et données numériques, Extrait du Volume 5, années 1917 à 1922) Pp. viii + 1537–1675 (Paris Gauthier-Villars et Cie; Cambridge At the University Press, Chicago, Ill: University of Chicago Press, 1926) 56 francs

The present section of this work deals with animal and plant physiology and biochemistry, and consists of tables extracted from papers published during the years 1917-1922, arranged under appropriate headings. Very varied information may be found within its pages Thus weightrelationships, the chemical composition of organisms and their organs and tissue fluids, and the toxicities of drugs are all included. The greater part deals with plant physiology and chemistry, but data on enzymes and the biochemistry of vegetable products are frequently of use to animal physiologists data are given in French, but the table of contents is also given in English, German, and Italian They are compiled from a selected list of about sixty different journals. The work should be useful for quick reference on any particular subject.

Vorlesungen uber landwirtschaftliche Bakteriologie. Von Prof. Dr F Lohnis. Zweite, neubearbeitete Auflage. Pp. viii + 400 + 10 Tafeln. (Berlin: Gebruder Borntraeger, 1926.) 22.50 gold marks.

The first edition of this book was published in 1913 and was regarded as a landmark in the development of agricultural bacteriology. Since that date, although the subject has advanced rapidly, no further edition has appeared, if the small book written in English in collaboration with Prof. Fred of Wisconsin be excepted. The present edition will therefore be welcomed by agricultural investigators, for though retaining the general form of presentation adopted for the original edition, the general results of the last fifteen years' research are incorporated, making the book essentially a modern text-book.

Practical Physics By T. G. Bedford. Pp. x + 425. (London: Longmans, Green and Co., Ltd., 1926) 10s. 6d net.

The course of practical physics described in this book, which is based on manuscript notes used in the Cavendish Laboratory, covers the first year's work of the average student preparing for Part 1 of the Natural Sciences Tripos Most of the experiments are simpler than those performed in the following year, which are unfortunately only partially described in Dr. Searle's text-books. The short introductory section contains valuable general instructions, and the book will be particularly valued by those teachers of physics who have had the privilege of passing through Mr. Bedford's class.

## Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

#### Double Innervation of Striated Muscle.

In the Proceedings of the Anatomical Society of Great Britain and Ireland, just published in the Journal of Anatomy, there is a record (page 498) of a communication by Prof. H. H. Woollard on the innervation of voluntary muscle, which is of unusual importance from its bearing upon a question that is a matter of widespread controversy at the present moment My purpose in directing attention to Dr. moment Woollard's observation, however, is not so much to emphasise its intrinsic significance as to suggest the possibility of an interpretation other than that adumbrated in his preliminary note.

of nerves proceeded to the same muscle fibres. Then the matter began to attract widespread attention, which was largely due to the fact that the attempt was being made to interpret the phenomena of muscle tone in terms of the assumed sympathetic nature of the non-medullated nerves After Prof. Boeke brought his preparations to London in 1921, my colleague J P. Hill suggested to the late Prof. Kulchtsky, who had just come to work in this Department, the desirability of investigating once more the problem that had been the subject of his first original work thirty years earlier.

In 1924, Kulchitsky published the results of this new research on the innervation of the muscles in snakes, in which he demonstrated once more, as Tcheriev and many others had done previously, that the two types of nerves did not pass to the same muscle fibres In other words, he was unable to discover any muscle fibre receiving both kinds of nerve fibres. Hence there emerged a sharp conflict between the results obtained by Bocke on the extrinsic muscles of the eye in mammals and by

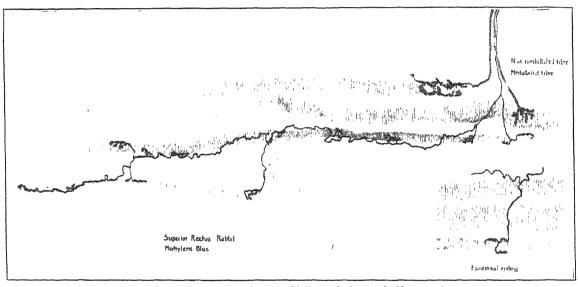

Fig 1.—Dr Woollard's preparation of a rabbit's muscle showing double innervation

For more than fifty years the problem has been discussed whether striated muscle has a double nerve supply (in addition, of course, to the sensory nerves connected with the muscle spindles). Interest in this question has been revived during recent years by the observations of Prof. Boeke, of Utrecht, who claims that each individual muscle fibre is provided with two nerves, a medullated somatic fibre and a non-medullated fibre, which he regards as being

sympathetic in origin.
When, in 1879, Tcheriev directed attention to the fact that the two types of efferent fibres, which twenty years previously Lionel Beale and others had detected in motor nerves, proceeded to different kinds of terminals, the medullated (Beale's "dark-bordered fibres") to the end-plates of Kuehne, and the non-medullated (Beale's "fine pale fibres") to grape-like endings, little attention was paid to the observation. For the opinion was then current that the fine musclefibres—even perhaps the spindles—and their nerves were the embryonic forms of the larger muscle fibres and their medullated nerves (see Koelliker's Crooman Lecture in 1862).

In 1909 and the succeeding years Boeke revived interest in the matter once more. He dissented from the earlier observations by claiming that both kinds Kulchitsky on the subcutaneous muscle of the body in snakes.

During the last three years the question of the innervation of striated muscle has become a matter of acute controversy. Doubt has been thrown upon the existence of non-medullated fibres in motor nerves, and in particular upon the claim that the nonmedullated fibres were derived from the sympathetic; and alternatively the suggestion has been made that the type of innervation found by Kulchitsky in the

snake might not be found in mammals.

Using the methylene blue method of staming, Dr. Woollard (after a very prolonged and laborrous search) has been able to demonstrate (see Fig. 1) in the case of the superior rectus muscle of the rabbit, a double innervation conforming to that described by Kulchitsky in the case of the snake. The rabbit's eye-muscle, like that of the snake's body, consists of two kinds of fibres, coarse and fine. In both cases the coarse fibres are more than double the diameter of the fine fibres, and whereas the coarse fibres receive medullated nerves proceeding to typical end-plates, the finer muscle fibres receive only non-medullated nerves proceeding to grape-like endings, placed epilemmally upon the muscle fibres. Moreover, these endings are disposed in such a way (a number of them being connected with a single nerve fibre widespread on several muscle fibres) as to make it impossible that they could develop into the ordinary end plates. Incidentally, the new observations of Kutchitsky and Woollard that the medullated fibres end hypolemmally and the non-medullated epilemmally, settle once for all the old dispute of sixty years ago (Kuehne, Koelliker, Beale, Margo, Rouget, Naunyn, and Engelmann) as to whether motor nerve fibres did or did not perforate the sarcolemma. As some do and others do not, each group of controversialists had some evidence to support their claims.

The importance of Dr Woollard's demonstration has in the fact that it removes once for all the doubt as to the existence of this type of double innervation in mammals. It also proves that the two types of muscle fibres (and associated nerve fibres) are morphologically distinct one from the other. In his communication, however, Dr. Woollard lays particular emphasis on the fact that he has found this type of double innervation only in the case of the eyemuscles and not in any other part of the body

It is important, however, not to lose a sense of perspective in estimating the meaning of this observation. In 1882, Dr. L. Biemer, of the University of Strasbourg, described (Archiv f. milr Anatomie, Bd. 21) non-medullated nerves ending in the muscles of the tongue and limbs in the riog (see in particular his figures 13 and 20) in precisely the same manner as Dr. Woollard has depicted in the case of the eye-muscles of the rabbit. The coincidence is

most striking and significant.

In view of these facts, especially when taken in conjunction with the difficulty Dr Woollard himself experienced in discovering such endings in the eyemuseles, the failure to obtain satisfactory proof of the presence of such nerve fibres in other mammalian muscles should not be assumed to imply their absence. When they are found so widespread in the muscles of the trunk, limbs, and tongue of amphibia and reptilia and in the ocular muscles of mammals, there is a presumption that one is dealing with a morphological fact that applies to all striated muscles. But it remains for future research to provide conclusive evidence for or against this morphological inference—a problem that Dr. Woollard proposes to investigate in the University of Adelaide.

University College, London, W.C.1, July 20.

#### Banded Structure in Aluminium and Copper.

IT is a well-established fact that copper, gold and silver, in the native state, exhibit twinning on the octahedral plane

I have recently examined, by means of X-rays, structures in aluminium which resemble lamellar twinning, and a sample of native copper which contained large well-marked lainellar twins. Such structures are always to be found in copper and its alloys, as well as gold and silver, if the metal has been worked and annealed, but are rarely found in cast metals. In aluminium they are rarely met with, although this metal has the same crystal lattice. The orientation in both parts of the 'twin' were determined. Two samples of aluminium were investigated, which showed the same relationship existing between them. These appeared to have one dodecahedral plane in common, but the one could only be derived from the other by turning one upside-down and rotating through an angle of 60°. The plane of junction between the crystals had no relation to the crystal structure of either. This was also the case

in the copper sample. Here there appeared to be no important crystal plane or direction which was common to both parts.

It has always been assumed that the banded structure in these metals represented twinning on the octahedral planes of the crystal, but the examples quoted above show that this is not always so It will, of course, be necessary to compare a number of samples of all the metals mentioned with the view of arriving at any definite conclusions

C F. ELAM

# Acarine Disease and the Muscles of the Honey Bee.

THREE years ago, Dr. Rennie suggested to me that as a part of the research on acarine disease of the honey bee. I should attempt to describe certain pathological appearances in the indirect muscles of the wings, since visible pathological conditions of these muscles are often, but not invariably, associated with acarine disease. The results of the investigation will be published in two parts shortly, and this letter contains the announcement of some of the main conclusions with a plea to biochemists to study these particular muscles of the bee in detail, since they seem to lead to an exceptionally clear path to the cause of contraction of muscle.

Before the pathological appearance of muscle could be accurately described, it was necessary to know the appearance of muscles which were deemed healthy since they were removed from lively bees which showed no signs of any of the known bee diseases. A thorough review of the literature showed that on the histology of the muscles there was no work sufficiently detailed or accurate to be accepted as a basis on which to describe pathological conditions. In fact, the muscles have been greatly neglected, and no description exists which includes, with the appearance of the contractile elements, an account of the nuclei, sarcosomes (reserve 'food' material placed between the contractile elements), innervation, tracheation, attachment to integument, and blood supply of any of the muscles of the bee. The literature on the muscles is very incomplete, scattered, and often inaccurate, and even the somatic musculature has been so neglected that many of the most important muscles are not recognised.

The first part of my paper attempts to deal with the name, function, innervation, tracheation, method of attachment and probable blood supply of every muscle or system of muscles in the three castes of Apis mellifera L. of different races, and it includes histological descriptions of fresh and variously prepared fibres as well as a brief description of their chemical composition and a note on their appearance under polarised light. The course of air through the tracheæ and the physiology of the nervous system in regard to the musculature is also considered. The second part of the paper deals with pathological conditions of the muscles.

Histologically the muscles of the adult bee can be classified as either fibrous or tubular. Fibrous muscle is characterised by its fibre being very easily split into 1000-2000 sarcostyles (fibrils) which are the apparent contractile elements of the muscle. The nuclei are scattered in many rows throughout the thickness of the fibre. Corresponding to the transverse striation of the fibre, there occur layers of semi-fluid substance (sarcosome substance) which seem to be utilised directly during the contraction of the fibre. Fibrous muscle is confined to the four large muscles attached to the walls of the thorax. These muscles are called the indirect muscles of the wings, since by altering the shape of the thorax they raise and lower the wings for

flight. Tubular muscle includes all the other muscles such as somatic, splanchnic, cardiac, doisal diaphragm, ventral diaphragm, and muscles of the reproductive organs. Its fibre is usually a tube with a narrow lumen in which lies a single row of nuclei. The sarcostyles forming the wall of the tube are very firmly bound together and I have not detected sarcosomes between them. There is no unstriped muscle in the bee.

Two different pathological states of fibrous muscle may be associated with a carine disease in bees. They differ in appearance and have their origin in different physiological conditions. They may occur together or singly or be absent in a bee harbouring Acarapis wood Rennie in its trachex

The case in which some muscle fibres degenerate, becoming white, brittle, and unable to contract, is due chiefly if not entirely to the blocking of the first thoracic spiracle(s). The diseased condition of the muscles can be produced experimentally (cf. White, Trans Roy. Soc. Edinburgh, 52, 1921) by artificial blocking of the anterior spiracle(s). The obstruction of the spiracle(s) interferes with the forward direction of the respiratory current of air, and with the obstruction is associated an inhibition or complete arrest of active flight. Young bees seem able to resist the consequences of the loss of flight better than old bees. In the case of 'crawlers' whose tracheæ do not contain many mites, and in the case of active flying bees whose tracheæ contain numbers of mites, it seems to be a matter of how the mites lie in the tracheæ and of many other factors which have to be determined for each bee.

Once flight has stopped the bee ceases to defæcate, thereby setting up many troubles of metabolism in all parts of the body. The fibrous muscles are the seat of very active metabolic changes. A supply of oxygen is essential for long-continued muscular activity, and from the lustology of fibrous muscle it seems legitimate to assume that most of the oxygen would be received from the tracheoles while the rest comes from the blood. The semi-fluid sarcosome substance consists apparently of albumin, glucose, the respiratory pigment, cytochiome, lecithin, and perhaps other lipins and probably various inorganic salts apparently acts as a reserve 'food' substance, passing m and out of the sarcostvles in a perfectly regular manner, depending on their state of contraction, and it is also very intimately united with the tracheoles. Presumably it is being constantly replenished by the blood and tracheoles in a healthy bee. Should the blood be loaded with toxins as the result of the non-defæcation of the bee, it seems probable that it would deposit some of its poison in the food-store for the muscle fibres, and this would be extra harmful if the fibres were already suffering from an impoverished oxygen supply from the tracheoles.

The waste products of metabolism resulting from muscular contraction can only pass away via the blood and tracheæ. During acarine disease the lumen of the tracheæ is liable to become obstructed, and if so a path for vital reactions is closed. When this happens the sarcosomes lose their orderly arrangement and become very much enlarged by coalescence with one another, probably because they are chemically very unstable and require the balance which is supplied only by the properly functioning tracheæ. Once the stability of the sarcosomes is affected, the contractile elements depending on them are thrown out of action, and so the muscle fibre suffers a change leading to death if the obstruction of the tracheæ is continued for long.

The other case, in which portions of muscle fibres assume a brown or black colour, seems the effect of

oxidation of a substance in the blood, probably dioxyphenylalanme, which turns black in the presence of oxygen, an alkaline oxidase, and water. The dark pigmentary colour of the bee, and probably also the blackening of the tracher in acarine disease, are probably due to the same substance. The darkening of the muscle, ie deposition of pigment in a fibre, does not seem to affect the contractibility of the fibre or to interfere greatly with its normal metabolism. It is the normal reaction to direct injury of normal tissue bathed with blood, and it can be produced experimentally with case. It assumes its deepest colour where apparently there is most oxygen, i e. near a trachea. The same holds true when it is associated with acarine disease, when presumably it is the result of mechanical mjury to the muscles by the mite In acarine disease the darkening very rarely occurs alone Almost always it is near a trachea in the centre of a fibre or part of a fibre which is degenerating and becoming whitish and brittle

Marischal College, University of Aberdeen.

# Discovery of Stone Implements of Lower Palæolithic Age in Ireland.

For many years past, as is well known, the prevailing opinion among archæologists has been that no traces of palæolithic man have come to light in Ireland; and it has been generally believed that he never lived in that country. During recent visits to Rosses Point, Sligo, I had considerable opportunities of examining the coast sections and the beach material

Fig. 1—Three views of large racloir in limestone from Rosses Point, Sligo.

there exposed, and I have been so fortunate as to discover a series of implements, and flakes, in limestone which, by their provenance and forms, I do not hesitate to refer to the Lower Palæolithic (Early Mousterian) period.

On the western, or seaward, side of the middle limestone promontory at Rosses Point, which separates Drumchiff and Sligo Bays, there are to be seen the remains of a rock-shelter. The shelter has a south-

Fig 2 —Fan-shaped ractor in limestone from Rosses Point, Sligo

westerly aspect, and now occupies an area of about 47 feet by 9 feet. The floor is 5 feet above present high-water mark, whilst the roof is 8 feet above. These measurements are taken at the back of the shelter. Covering what is left of the roof is an Early Neolithic raised-beach consisting of powdered shelts to a depth of I foot. The outer margin of this beach rests in a hollow in the Boulder Clay which formerly

covered a portion of the headland, but was partially eroded in Early Neolithic times. Under the large blocks of rock, evidently fallen from the roof of the shelter, I found more than 100 unrolled flakes and flake implements made of limestone. Some of these flakes are very large and weigh so much as 36 lb. The artefacts discovered may be classified as follows:

Levallois-like flakes. Side racloirs (Fig. 1). Fan-shaped racloirs (Fig. 2). Choppers. Ovate hand-axes. Pointed hand-axes (Fig. 3). Square-ended scrapers.

A little more than a mile to the south of the abovementioned site, upon Coney Island, the remains of a large cave may be seen. It is now 50 feet wide, 4 feet high, and 6 feet from back to front The

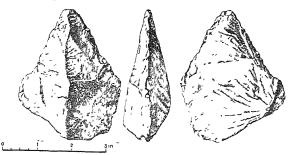

Fig. 3 —Massive hand-ave in limestone from Rosses Point Sligo

cave faces north-east and its floor is below the level of high tides, with the result that the contents have been drifted out and along the coast for a distance of half a mile, and are now found there upon the beach. These implements, two of which are remarkable examples of Lower Palæolithic workmanship, are, as would be expected, rolled, and exhibit on their surfaces marks due to collision with other stones.

In addition to an examination of the sites at Rosses Point and at Coney Island, I have carried out a close investigation of the sections of Boulder Clay visible upon the coast, and at Ballyconnell, situated

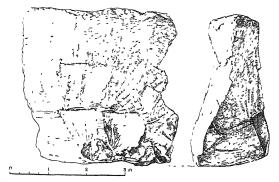

FIG. 4.—Prepared core in limestone found in situ in Boulder Clay at a depth of 39 ft from the surface at Ballyconnell, Sligo.

5 miles to the north-west of Rosses Point, I discovered, in situ, at a depth of 39 feet from the surface of the ground and embedded in Boulder Clay, a core, with facetting upon both platforms, and a massive flake used as a hollow-scraper, formed of limestone. One of these specimens (Fig. 4) weighs 12 lb., and exhibits glacial striæ on both faces. The occurrence of the artefacts in Boulder Clay affords conclusive evidence of their antiquity, and, apart from any other circum-

stances, makes it in the highest degree probable that the other specimens of the same type from Rosses Point and Coney Island are older than the Boulder Clay represented at Ballyconnell. The section at this place shows the following strata:

> Landwash, 4 feet. Boulder Clay, 35 feet. HORIZON OF FLAKE IMPLEMENTS Boulder Clay, 7 mches. Middle Limestone.

From the researches  $\boldsymbol{I}$  have carried out it seems clear that the specimens:

 $(\alpha)$  are of undoubtedly human origin, and of Lower Paleolithic (Early Mousterian) types,

(b) are older than a deposit of Boulder Clay present upon the Sligo coast; and

(c) have a considerable distribution, and are not confined to one site only.

The surfaces of the artefacts exhibit a different colour from the freshly broken limestone, and some show patches of what appears to be a very definite patination. The material from which the specimens are made has a well-marked conchoidal fracture, and was very skilfully flaked by the palæolithic hunters of Sligo.

I hope in the near future to publish a full and illustrated account of my discovery.

J. P. T. BURCHELL.

30 Southwick Street, Hyde Park, W.2.

I have examined a large series of the remarkable specimens collected by Mr. Burchell in Sligo, Ireland, and, at his request, I add a few lines to the preliminary note on his discovery. In the first place, I have no doubt that these specimens were flaked by man, and, secondly, that their forms are such as were made in Lower Palæolithic, Early Mousterian, times. Though I have not yet visited the sites where Mr. Burchell has worked in Ireland, and am thus not able to testify, from personal observation, as to the soundness of the geological evidence upon which he relies, yet I believe, after a study of his carefully recorded details of the provenance of the specimens he has found, and an examination of one of three artefacts discovered by him embedded, at a depth of 39 feet, in Boulder Clay at Ballyconnell, that this evidence is satisfactory. Many of the Sligo implements are of impressive size and appearance, and I hope it may be possible, in view of the manifest importance of Mr Burchell's discovery, to publish accurate wash-drawings of these, J. REID MOIR. of the natural size.

One House, Ipswich.

## Evolution: Emergent and Resultant.

In adhering to the position already outlined (Nature, July 16, p. 81), I should like to suggest further that there is a fundamental distinction between what happens to be inferable "on the basis of existing knowledge," and what is not inferable under any intellectual conditions whatsoever. (In the present connexion 'inferable' is more relevant than 'deducible,' since not deduction alone, but all forms of inference, are legitimate.) What was not inferable by their predecessors, for example, was inferred by Newton and Darwin themselves. But it is often argued that the existence and qualities of certain "integral wholes" can never be inferred and explained from "the most complete knowledge"—not merely "existing knowledge"—about their constituents possessed by any finite mind whatever. (I exclude infinite mind in order to limit the discussion.)

This position appears to me to be quite unjustified

by the essential tendencies of modern research. As soon as knowledge ceases to be merely elementary (and with all its limitations, this at least is true of modern knowledge), its realised content yields plain indications of the nature, scope, and potentiality of knowledge as knowledge. We begin to understand both what knowledge is capable of doing and also why it possesses this capacity, even while we realise the drastic limits of its immediate advance, nor can it be objected that this issue is not strictly scientific, since epistemology stands on precisely the same footing as physics, how minds know, in other words, is fully as scientific a problem as how bodies move We are concerned, therefore, not only with the established content of knowledge, but also, and to a still more important degree, with the intrinsic nature of knowledge.

From this point of view, Prof Lloyd Morgan's criterion seems to afford a merely relative distinction between emergents and resultants; since, as knowledge expands, the first must obviously fall within the second. We require, therefore, as he suggests, some method of regarding certain "integral wholes as being at the same moment (a) inferable in principle and (b) unprecedented in character, and so undeniably emergent I venture to suggest that this situation resolves itself into the evolution of existentially new syntheses whose nature, and the nature of whose elements, are fully knowable (in principle) by finite minds, which can also infer that such syntheses will necessarily and causally precede processes hitherto non-existent Television exemplifies this situation on a relatively simple scale, and the immortal drama of the future on a much more complex scale; and in this connexion two further essential features must be considered The first is the degree of complexity presented by the structure of the synthesis; the second, which is obviously closely associated with the first, is the degree of contrast with earlier syntheses. When the contrast is slight, as in the summations mentioned by Prof. Lloyd Morgan, emergence scarcely

Thus both television and the future drama are emergent, because both, taken in their entirety, are unprecedented, despite their widely differing forms At the same time, each is the final culmination of antecedent tendencies, which are never (in principle) indiscernible as data for inference; whether they can be so employed or not depends on the intellectual capacity of the investigator. In principle, therefore, every "integral whole" and all its effects are inferable and, consequently, also resultant But if, like finite mind at its first origin, any had never pre-existed, it would equally be emergent; while if, like the earth's future revolutions, any had pre-existed, then it would be not emergent but resultant only. Emergence thus becomes an additional characteristic, or quality of a higher order, the differentia of which is marked, or even absolute, existential novelty. Every emergent arises like Aphrodite from the foam, unparalleled—once again the element of contrast—but not therefore inexplicable and non-inferable. If, then (as a final concrete example), the biochemical synthesis of living organisms is effected within the next few decades (as is by no means impossible), these should, in my opinion, be regarded as emergent for two reasons: (a) because they would share the emergent quality of life as such; (b) because, as artificial, they would be unprecedented; while (c) they would also be completely explicable and inferable from man's actual precedent knowledge.

## Diamond-glass Fluorescence.

That fluorescence may result when a glazier's diamond is drawn over the surface of a pane of glass was shown by Foley many years ago (Science, N.S., vol. 13, No 332, May 10, 1901). This phenomenon may be studied indirectly in two ways. (a) by ruling with a diamond on the back of a photographic plate, (b) by placing a clear glass plate on the film side and ruling on that. In either case on development a distinct darkened band will appear (if there was fluorescence) the width of which depends on the thickness of the glass plate that was ruled and the angle of total reflection. In (a) the affected portion of the film is of course on the under side next to the glass, and the development consequently is considerably slower than in (b), where the exposure is on the tront side of the film. The angle of total reflection in either case is given by the relation

$$d=2t \tan \theta$$
,

where t is the thickness of the glass plate and d the width of the band.

The phenomenon that attracted my attention, and prompted this note, may be briefly described as

Recently, while cutting photographic plates into strips for a special purpose, it was noticed that the bands for the particular diamond used were oftentimes only half the width of those described by Foley, also that if the bands did appear on both sides they were generally of unequal density; and, moreover, one or the other of the bands were occasionally found to be discontinuous, or even both sides disappeared, only farther on to have reappeared again. It was observed that a full-width band may result when the 'cut' is a scratch, or even when the diamond glides over the surface without leaving a trace. In every instance when fluorescence was produced under conditions other than those when the diamond 'rings clear,' the resulting band was full width. In other words, a new diamond that is perfect in its cutting qualities may, when fluorescence accompanies the cut, produce a half band, or a full-width band in which one-half is more dense than the other. Why this results may be explained by reference to

Fig 1.

In Fig. 1, a, the diamond is shown held at the cutting angle and drawn to the left. The resulting cut or crevasse opens in advance of the cutting edge, and ultimately may open up entirely through the plate, as shown. This crevasse forms a totally reflecting surface confining the light emanating from the point of contact (which is at the side of the diamond and not at its tip) wholly on one side, as shown in Fig. 1, b. The band begins abruptly at O, increasing in density to the right, and ends abruptly when the critical angle is reached at D.

If the other side of the diamond produces fluorescence also, then the total width of the band is 20D.

However, this half, as stated before, may differ widely in density from the first. If the diamond is a poor one and scratches or merely rubs the glass surface, the resulting band, if present at all, is always of width 20D

Others may also have observed the one-sidedness of this phenomenon when using a new glazier's diamond.

## Atmospheric Electricity.

IN NATURE of Mar. 5 (Suppt, p. 6), Dr. Chree gave an excellent review of my book." Die elektrische Leitfahigkeit der Atmosphare und ihre Ursachen." (Vieweg und Sohn, Braumschweig, 1926), which will appear in English within this year. I am much pleased to see that Dr. Chree, who is an authority of world-wide reputation in atmospheric electricity, finds my book valuable and not inferior to the recent French monographs on atmospheric electricity by the late B. Chauveau and by Dr. Mathias and his co-workers.

Nevertheless, I should like to make a few comments upon Dr Chree's review in order to remove one or two misunderstandings. Dr. Chree seems to object to my use of the term "Kennelly-Heaviside-layer" instead of "Heaviside-layer." I thought I was justified in using the first expression because in the American journal Science (1925) it was stated that Kennelly was the first to postulate the existence of the conductive layer in the upper atmosphere, and not Heaviside. If in this I am wrong, I will gladly alter this in the English edition of my book

At the end of his review Dr Chree says . "Dr. Hess does not, however, seem to notice that if the somewhat serious defect in the Ebert apparatus, which he accepts as proved by Prof. Swann, really exists, then much of the information which appears in the present book and elsewhere respecting negative ions must require correction." To this I must add that in choosing the numerical data on ionic numbers for my book I tried to select only those taken in places where the apparatus was well screened from the electric field of the atmosphere Observations taken under these conditions are fortunately more numerous than those unscreened in the open air, and therefore I believe that the data given in my book require no correction whatever From my own experience I should think that the effect of the earth's field disclosed by Swann was overestimated in some cases, and that the distribution of ions, as found in electrically well-screened places (under the leaves of trees, m open windows, verandahs, etc ), is not very different V. F. HESS. from that in the open air

University of Graz.

Austria

WITH regard to the 'conducting layer,' my objection was to associating it with the name of either Heaviside or Kennelly. It would probably be best, as in the case of the 'penetrating radiation,' to attach no personal name, but if a name is to be attached, the claims of Balfour Stewart, as I have already explained in the columns of Nature, seem to me to come first.

With regard to results from the Ebert apparatus, I noticed no explicit statement in the text that only those stations had been included where the apparatus was specially sheltered, and in at least one or two of the cases mentioned I had reason to believe that the contrary was the case. I am personally inclined to share the doubt now expressed by Prof. Hess whether

Prof. Swann's unfavourable conclusions are in actual practice fully justified. Some experiments, in fact, made at Kew Observatory by Mr E H. Nichols ("Terrestrial Magnetism and Atmospheric Electricity," 1916, p 87) did not confirm Prof. Swann's conclusions But there seems no reference to these in Prof. Hess's book, and I had supposed him to accept Prof. Swann's conclusions without reserve. My own view is that an independent investigation into the conditions under which the use of the Ebert apparatus is wholly satisfactory would be useful. I am glad to hear that we may expect an English version of Prof. Hess's valuable book.

### The Depth to which Whales Descend.

When a whale is attacked, it usually attempts to escape by 'sounding' or going vertically down; the rope it takes out on these occasions is a good measure of the depth it descends to, and the attacking boat, owing to the strain on the line, an indicator of its position under water

The Right-whales appear to descend to greater depths than the Fin-whales, and on this account to be more easily captured. When the Greenland whale is attacked, it usually leaves the surface and descends immediately; it takes out rope very quickly and soon reaches a great depth. After a time it reappears near where it went down in an exhausted condition and is easily captured. Large ones appear to descend to a depth of 700-800 fathoms and remain under water nearly an hour. Sometimes the Greenland whale dies at a depth of 800 fathoms, and sometimes, as related by Scoresby, if the depth of the water is not sufficiently great, it strikes the bottom while descending and kills itself in this way; in both cases it has to be hauled up dead

It is only when it is attacked in very deep water with the hand or simple gun harpoon, as in former days, that the Greenland whale descends to a great depth and that the boats engaging in its capture require to carry a very long line; in water of moderate depth a much shorter one suffices. This fact is surely in itself a sufficient answer to those who, on purely theoretical grounds, deny that whales can descend to great depths.

The blubber of whales appears to be related in some way to the depths to which they descend. In the Greenland whale, for example, it is very much thicker than in its congener the narwhal; perhaps its great thickness enables it to withstand the pressure at great depths?

R. W. GRAY.

## Ophion luteus.

The shrill sound of this fly is here a sure nocturnal herald of the Dog Days. Nearly six years ago I described in Nature (Nov. 10 and Dec. 1, 1921) how some members of my household had been stung by the fly; but it was not until last night that I was favoured by its attention. The weather being very sultry, I was sleeping under a single sheet when I was awakened by a sharp stab in my thigh. Clapping a hand on the place, I missed the intruder; but immediately after was stung on the left arm and this time caught Ophion luteus

The incident would not be worth recording were it not that it puzzles one to understand what can be the motive in this fly, when not molested, in thrusting its ovipositor into a human being. It would be interesting to hear whether other persons have received similar attention from this or any other species of Ichneumonidæ.

## Some Colouring Agents in Glasses and Glazes.1

By Sir Herbert Jackson, K B E., F R.S,

Director of Research, British Scientific Instrument Research Association

THE colouring agents of glasses and glazes are very many; moreover, several of these agents can impart colour to glasses or glazes in what may be described as different ways. An explanation which would include all our present knowledge of the behaviour of any one of them would occupy a long time. I have chosen two colouring materials, copper and iron, and propose to deal with some of the effects which can be produced by them and their compounds. I should like also to make a few remarks on certain effects which can be produced by radiations such as ultraviolet light, X-rays, and gamma-rays from radioactive materials

I have chosen copper and iron because, in their various modes of action as colouring agents in glasses and glazes, they illustrate fairly completely the manner in which most of the materials used in this connexion behave. For present purposes I will not draw any definite distinction between glasses and glazes, but will use the terms somewhat

indiscriminately.

Copper can be introduced into a glass or glaze so as to produce reds, browns, yellows, greens, blues, purples, and black. In some instances the colours can be well seen by transmitted light; in others the material is too opaque to show the colour except by reflected light. These various effects are produced by compounds of copper or by metallic copper itself. Of the compounds of copper, attention will be especially devoted to the two oxides of copper, cuprous oxide and cupric oxide. Cuprous oxide is the colouring agent in the brilliant scarlet Egyptian glass, specimens of which appear to be correctly attributed to at least as far back as the XVIII. Dynasty and up to Roman Egyptian times. It would appear from the absence of any specimens attributable to more recent times that the knowledge of how to produce this glass successfully was then lost.

Microscopic examination of a specimen of the scarlet Egyptian glass given to me some years ago by Prof. J. N. Collie, and of other specimens given to me more recently by Mr. Horace Beck, showed that the colour was due to small crystals of cuprous oxide. Chemical examination of the glass itself revealed that it was an ordinary lead glass containing about 30 per cent. of lead oxide, and the quantity of cuprous oxide varied from about 8 per cent. to 10 per cent. Based on this information the glass was successfully made after a few trials. During those trials yellow crystals were often observed in parts of the glass, and recently Mr. Horace Beck provided me with an orange yellow bead found at Faversham, in Kent, the colouring matter of which was again identified as cuprous oxide, but mainly in the yellow form. The red form of cuprous oxide is the better-known form, and is produced when copper is heated in a

<sup>1</sup> Discourse delivered before the Royal Institution on Friday, Mar. 4.

limited supply of air; it can generally be well seen on the underside of the black scale detached from a piece of metallic copper which has been heated for a short time to a high temperature in air and then kept at a lower temperature for some time.

A ready method of producing the red oxide is to add a solution of copper sulphate to a solution of glucose and then to add caustic potash to the mixture. On heating the clear blue solution so obtained, reduction of cupric oxide by glucose occurs, with consequent precipitation of red cuprous oxide. At the first stage of heating it is generally possible to notice the formation of a yellow precipitate mingled with the red, these colours can be better shown by using Fehling's solution, which is made up from copper sulphate, Rochelle salt, and caustic potash, and is a clear blue solution. If a small quantity of the solution of glucose be poured into a large quantity of boiling Fehling solution the red oxide is formed If a small quantity of Fehling solution be added to a large volume of boiling solution of glucose, the yellow form is produced, and is permanent in the sense that it may become rather more orange in tint but does not reach the red stage.

Without going into the doubtful composition of this yellow form, in respect of the extent to which it may be considered hydrated, it may be remarked that if it is heated out of contact with air the yellow form persists, and is apparently completely freed from water at a temperature of about 350° C. The difficulty of making any statement about the temperature at which the yellow form can exist in glass will be appreciated if a short description is given of the behaviour of cuprous oxide glass

during its preparation

If the proportion of cuprous oxide introduced into the glass be about 8 per cent., the whole of it dissolves in the glass at the temperature of 1000° C. at which the glass is made. If the glass be quickly chilled from this temperature, no colour, except the almost unavoidable green colour due to oxidation of part of the copper, will be seen; the glass is a nearly colourless transparent one. On reheating this glass it is possible to produce, according to the temperature to which the glass is raised and the length of time during which it is heated, comparatively large crystals or aggregations of crystals of red cuprous oxide, smaller crystals of the same form, or particles so small as not to be recognised as crystals under the microscope Along with these are frequently obtained definite crystals of the yellow form, clouds of yellow particles, and, if the re-heating be gentle, the particles of yellow cuprous oxide are so small as to be unrevealable by the microscope, and what is obtained is a clear yellow transparent glass. Here, then, from two forms of one and the same oxide of copper, we have a range of colours associated with the proportions in which

No. 3016, Vol. 1201

the two forms are mixed in the glass and with the size of their particles What is the inner nature of the difference between the red and yellow forms which may account for their difference in colour is vet to be made out.

Much ancient Egyptian glass does not contain lead, but is mainly of the composition of an ordinary window glass—that is to say, its principal ingredients are silica, lime, soda, with varying quantities of potash, magnesia, and alumina. It has not been found possible to make the brilliant scarlet cuprous oxide glass satisfactorily in a glass of this composition The temperature required for the proper making of such a glass is too high for the persistence of the scarlet colour, and the resulting glass is of a brown or brownish-red colour. A scarlet coloured glass of the common soda-lime type could be made if the composition of the glass were so chosen that its fusing point was as low as that of the lead glass which the Egyptians used. If the Egyptians ever did make such a glass, it would have been so unstable that it could scarcely be supposed any specimens of it would have persisted to the present day.

Ancient brown glass of the soda-lime type just referred to appears to have been very widely distributed. Recently I have been given some beads of this glass which, I am informed, work up through the sand on the coast of Zanzıbar. Whatever attribution is given to the various specimens, they all seem to be very similar in composition and to depend for their colour upon the presence in the glass of minute particles of metallic copper. Whether the production of this brown or brownishred glass preceded that of the scarlet glass is a question which cannot be dealt with here. It is worth while, however, to refer to one property of cuprous oxide. This oxide does not form salts with acids except with the halogen acids: hydrofluoric, hydrochloric, hydrobromic, and hydriodic. With the oxygen-containing acids, if it re-acts with them, metallic copper is produced along with a cupric salt of the acid. With sulphuric acid this change takes place at the ordinary temperature; with a weaker acid, like acetic acid, the action is very slow unless the temperature is raised.

Taking these reactions as analogous to what may occur in a glass, and considering silica as a weak acid, it will be understood that if the temperature of a glass, either the lead glass or the soda-lime glass, be raised high enough, the result will be the production of metallic copper dispersed through a greenish cupric oxide glass. If the percentage of cuprous oxide used were high, about that used for the scarlet glass, there would be sufficient green to make the red of copper look, by reflected light, distinctly brown. With less copper present the colour would get nearer to a red, and it will be easily understood how, by using progressively less and less copper it would be possible to arrive at a glass resembling the wellknown red glass which owes its colour to particles of copper so finely comminuted as to render the glass quite transparent to the eye. The transparent red copper glass and the brilliant sang-de-bæuf

Chinese glazes are made under conditions which tend to reduce any cupric oxide which may be formed, so that the resulting glass is not rendered dingy by a green tint, due to dissolved cupric oxide, marring the brilliant red due to the dispersed metallic copper. It should be added that for this brilliant glass so little copper is used (it is in the neighbourhood of 05 per cent) that any colour from cupric oxide which would arise from such a change as is mentioned above under the action of silica would be so pale as to have practically no effect on the brilliance of the red due to the

dispersed copper.

Here, then, we have again considerable variations in the appearance of the glass dependent upon the size of the particles of the colouring agent dispersed through it, and this is made evident when thin pieces from different portions of glaze from one and the same Chinese sang-de-bouf vase are examined by transmitted light Under the microscope, for example, some pieces are distinctly red, others are purple, others again are blue, and others look like neutral coloured glass. Closer study shows that in the most brilliant red portions no particles can be seen by the microscope. In some of the less transparent red pieces, particles are revealed either by a cloudiness or as discrete particles. In the purples these particles are larger, and in the blues they are still more marked, while in the neutral colours the particles are generally seen less closely packed but distinctly larger in size.

The colours produced by cupric oxide in glasses and glazes need not be dealt with in detail, as there is much common knowledge about these. One or two points not in common knowledge may, however, be emphasised. In a glass of the same composition, cupric oxide may give a very marked blue colour if the glass is made at a comparatively low temperature (1000° C. to 1100° C.); whereas with the same concentration of copper and the same glass made at a higher temperature, about 1300° C., for example, there is a very marked green shade in the blue. It is worth pointing out that the blue low-temperature glass is green while hot.

It would lead us into too much detail to do more than direct attention to the possible analogies between the action of water in solutions of cupric salts and the action of the oxides of the alkali metals in glasses coloured by cupric oxide. The change from blue to green just mentioned in the case of the low-temperature cupric oxide glass calls to mind the fact that a green solution of cupric chloride, which becomes blue when sufficient water has been added, becomes green again on heating it. A study of the changes of colour which can be produced in aqueous solutions and salts, and of the methods of modifying these colours, has been of great assistance to me in shortening the experimental work necessary to arrive at the compositions of a number of glasses in which it was desired to produce certain colours either with copper or other colouring agents.

As an example of the change of colour effected by adding water to a salt, copper sulphate may be mentioned. This salt, in its anhydrous condition or with only one molecule of water, is colourless Crystals containing five molecules of water are the ordinary blue copper sulphate crystals, and the solution of these in water is blue If we take boric anhydride and an oxide of an alkali metal as analogous to sulphuric acid and water, a very similar story can be told A small quantity of cupric oxide does not dissolve in fused boric anhydride, but forms a white borate which is dispersed through the fused mass The addition of an alkalı will bring about solution and give a clear blue transparent glassy mass. The most striking example is to take boric anhydride and the alkalı lithium oxide in, say, three different proportions, such as one molecule of lithium oxide to one, four, and ten of borne anhydride With 05 per cent of cupric oxide the first is a fine deep blue, the second is a paler blue, the third is still paler; and if the proportion of alkali oxide be lowered until there is only just sufficient to bring about complete solution of the cupric oxide in the mass, there is but little colour to be seen at all.

With many glasses made at a high temperature, cupric oxide gives an olive-green colour. Without going so far as to say that the dusky shade in the green is invariably due to some reduction of the cupric oxide to the lower oxide of copper, there is evidence of this in certain instances which I have come across. To take one: in making trials for a glass which was intended to be of a green colour with only a slight tinge of olive in it, and of a sufficiently light shade to enable the light of a candle flame to be seen through a 1-inch thickness of the glass, the furnace conditions happened to change on one occasion so that the glass was exposed to a reducing atmosphere. The resulting glass was so black that a bright June sun was invisible through a piece of the glass one-fortieth of an inch thick. Such a state of affairs might be considered to come about by the glass being a mixture of red copper glass with a green cupric oxide glass, through which mixture but little light could be transmitted. Now red glass owing its colour to finely dispersed metallic copper is rendered colourless by fusing it and quickly chilling it. The black glass referred to might therefore be expected to become green if fused and quickly chilled, but it did not change from its intense black colour. This just gives a hint of the possibility of a cuproso-cupric compound being present in the glass analogous to, though not so definite as, ferroso-ferric oxide, the well-known black iron scale.

Again, an analogy with solutions helps a little. If to a colourless solution of cuprous chloride in hydrochloric acid there be added a transparent green solution of cupric chloride, the mixture turns black. Although dusky greens and the black glass just referred to might be accounted for by varying mixtures of red and green glass, the colour of this solution could scarcely be accounted for in the same way. Moreover, in experimenting with red copper glasses, and studying the way in which the red colour can be prevented from developing by sudden chilling and can be produced by subsequent

heating, I have repeatedly noticed that, instead of obtaining a clear colourless glass in bulbs made from the red glass and quickly chilled, the bulb has been sometimes of a dusky hue and sometimes of a definite neutral tint As no other colouring agent but copper was present in these glasses, I am inclined to attribute the neutral shade to a cuproso-cupric compound which is stable in the glass and is analogous to the compound formed when the cuprous and cupric chloride solutions are mixed, rather than to a physical mixture of

red and green glasses

I must not deal further with cupric oxide glasses except to mention that, unlike cuprous oxide glasses, copper glasses and many other coloured glasses, such as gold glasses, selenium glasses, cadmium sulphide glasses, and opal glasses, cupric oxide glasses cannot be rendered colourless by sudden chilling, nor, indeed, can the tint of these glasses be modified to any noticeable extent in An attempt to explain this difference, which seems to divide colouring agents generally into two classes, would involve a very lengthy account of the various phenomena which have been observed, and would, moreover, be to a considerable extent little more than a re-statement of facts which would involve differentiation between the meanings of such terms as 'solution,' 'chemical combination,' and 'dispersion,' and would lead to much argument I must content myself with this short and incomplete account of the modes of behaviour of copper and its oxides in glasses and glazes.

Passing on now to iron, there are colours produced by ferric oxide, ferroso-ferric oxide and ferrous oxide, but I do not know of any glass or any material which could be called glassy which owes its colour to metallic iron in a fine state of dispersion. Starting in the first place with ferrous oxide, which gives the well-known green colour to glass of the nature of window glass, I need only point out that this colour is considerably modified by the composition of the glass, and without going into a number of details I will mention the way in which this tint is modified by the presence in the glass of zinc oxide or magnesium oxide The former intensifies the colour produced by any given amount of ferrous oxide and changes the usual green into almost a blue. A similar change occurs with magnesium oxide, but the intensification of the colour is less marked Among the alkalis, lithium oxide also tends to give a bluish tint to glasses containing ferrous iron A notable example of this is seen in an early Chinese glaze which, through the kindness of Mr. G Eumorfopoulos, I had the opportunity of examining. The thunner parts of this glaze are practically colourless, but the thicker parts have a beautiful blue tint An examination of the glaze showed that it was for such glazes unusually rich both in lithium oxide and in magnesium, and the colouring material was identified as iron. If the Chinese workers had substituted zinc oxide for the magnesium oxide in their glaze mixture, the colour would have been very much more marked.

(To be continued.)

## The Control of Insect Pests by Means of Parasites.

By Dr. S. A. NEAVE.

In recent years agriculture in its broadest sense has received a powerful stimulus throughout the British Empire owing to the tremendous growth of the demand for vegetable and animal products of all sorts, especially in the more densely populated countries. In consequence, more and more attention has been directed to the insect and other pests of crops and domestic animals, and some recognition of the vast damage they do is becoming general. One result of this is that entomology, as an applied science, has attained a status and importance that would not have been thought possible a generation ago

The almost world-wide attention that has been directed of recent years to problems of insect pests has naturally led to the investigation of new methods of controlling them Though considerable strides on the chemical and physical side have been made in advancing our knowledge of insecticides and of apparatus for using them (even aeroplanes having been adapted for this purpose), it is now fairly widely recognised that such methods are seldom more than palliatives and necessarily involve an annually recurrent expenditure Indeed, it is not too much to say that the damage done by insects, when the cost of keeping down their numbers is added to it, materially increases the cost to the consumer of nearly everything he eats and much of vegetable and animal origin that he wears or uses in other ways. Artificial control measures have the further disadvantage that most of them are unsuitable for use by the uneducated native populations, who are yearly producing more and more of the crops of cotton and other tropical products that are exported to other countries

One of the primary causes of an insect becoming sufficiently numerous to reach the status of a pest is the action of man himself, who, in the processes of agriculture, destroys the equilibrium that exists under natural conditions between insects and their various enemies A pest with a somewhat different origin, and one often most difficult to deal with, is an insect that has been accidentally or thoughtlessly introduced into a new country where the climatic conditions may be specially favourable to it and the natural enemies that kept down its numbers in its native country do not exist. That this should have already occurred in the temperate regions of the New World and of the southern hemisphere is not surprising, and some of the worst pests in Canada, South Africa, Australia, and New Zealand are in fact of European origin and not indigenous in those countries Many examples of this might be cited, but one with which most people are probably familiar is that of the This insect, Codling Moth, which infests apples though not of any great importance in England, and seldom found in numbers except in neglected orchards, is a major pest in all the more temperate parts of the British Empire. Elaborate spraying operations have to be carried out against it, and these materially enhance the cost of imported

apples, while the fact that the best insecticide used for it contains arsenic has caused much loss and confusion to the trade in imported apples owing to the risk of arsenical residues being found on them.

Though every country now has a more or less elaborate code of quarantime laws directed to keeping out insect pests, they can never be an absolute safeguard, and it is too much to expect that what has happened in temperate climates will not repeat itself in tropical ones with the ever-increasing exchange of tropical products that is now going on Indeed, the history of recent years shows that this is already happening, as can be seen by the spread, within the last ten years, of the dreaded Pink Bollworm of cotton into the New World

Realisation of all this has led the modern entomologist to try to take a leaf out of the book of Nature, and to see whether what may be called artificial methods of insect control cannot at least be supplemented, and perhaps in some cases superseded, by utilising parasitic insects or other enemies to reduce the numbers of a given pest. Though this method obviously has great limitations and must be applied with great circumspection, it has the outstanding advantage that, if successful, its results are permanent, and that the expense it involves is limited to the original cost of the preliminary investigation and of the breeding, exportation, and establishment in its new home of the parasite concerned. It is not, however, suggested that this method can be expected to eliminate altogether the necessity for artificial control measures except in rare cases, since a parasite in the nature of things does not normally exterminate its host (a procedure that would involve its own extinction), but merely reduces its numbers to such an extent that a major pest may become one of mmor importance.

It is obvious that great care must be exercised in the carrying out of such a scheme, and certain cardinal principles are involved. Perhaps the chief of these is that in the majority of cases the parasite selected for introduction must be a highly specialised one that is unlikely to affect the balance of Nature in its new home by attacking anything but its intended host or a species nearly allied to it. It is also important to discover the most effective parasite of the many that commonly attack a given Harm may be done by the importation of several parasites, all of which compete for existence in the same host. Though there is some doubt on the point, it has been stated that in Hawan, where some of the pioneer work of this character has been carried on, when several parasites of the Mediterranean fruit-fly were simultaneously introduced into those islands, they ultimately proved less effective owing to the numbers of the most efficient species being reduced by competition with the others. Similarly, the utmost care has to be taken to eliminate all hyper-parasites, that is to say, parasites of the parasite itself, for these may practically cancel its effect on the host, and it must be borne in mind that once such minute insects are established in a new country their eradication is impossible. Moreover, a parasite that is only moderately effective in its native country may become vastly more so in a new one if its hyper-parasites are absent. It will therefore be obvious that the successful accomplishment of a scheme of this character involves much careful and often lengthy investigations sometimes extending over several years, and that satisfactory results cannot be guaranteed in advance

The Government of the United States has devoted large sums in recent years to establishing laboratories where work of this kind may be carried out, and early in the present year it passed an Act that appropriated no less than 10,000,000 dollars for work on the European Corn-borer, an

introduced moth that is doing a vast amount of damage to maize, and the parasites of which are being bred in France for export to North America.

In order that a start may be made on these lines in the British Empire, the Empire Marketing Board has recently provided the Imperial Bureau of Entomology with funds to maintain a laboratory at Farnham Royal Work has just begun there, but it is not to be expected that any important results can be attained before next year at the earliest, though it is probable that, as a small beginning, a Braconid parasite of the blow-flies that cause serious losses amongst sheep may be sent in the autumn to Australia, New Zealand, and the Falkland Islands. Several investigations have, however, been begun or are being planned, which, it is hoped, will benefit many other parts of the Empire, including Canada, Australia, New Zealand, South Africa, and Kenya Colony.

## News and Views.

An agreement between the I.G Farbenindustrie (the German Dye Trust) and the Standard Oil Company of New Jersey for the exploitation of a new process for the production of synthetic petrol which the I.G. has evolved, was reported in the Times of Aug. 11. This agreement relates solely to the American markets, and further negotiations, it was stated, may be expected with European countries in respect of the realisation of the patent rights concerned. Much speculation appears to have arisen as to the precise nature of the process in question, as only the most meagre information has been officially forthcoming. But the few details provided in the Times report are sufficient to identify it with reasonable certainty as that which forms the basis of a group of very recent patent applications emanating from the I.G. This new process, described as the destructive hydrogenation of carbonaceous materials, appears to comprise nothing more than a development of the well-known Bergius method, according to which coal or similar material is subjected to thermal decomposition in the presence of hydrogen under pressure to produce hydrocarbon mixtures of the nature of petroleum. But whereas berginisation is essentially non-catalytic, the new process is based upon the discovery that the introduction of certain catalysts leads to the formation of more valuable hydrocarbons, with increased yields and at an enhanced rate.

The first of these catalysts to be protected by the I.G. were compounds of nitrogen, whether added as such or formed in situ from added nitrogen; then followed molybdenum and its compounds, then chemically combined sulphur, then tungsten and chromium, until now a whole host of such substances have been described. Furthermore, the hydrogen need not be so highly concentrated as in the bergmisation method; it may even be present as combined hydrogen, e.g. as hydrogen sulphide or methane, or it may be produced by the introduction

of steam which reacts with the carbonaceous material. Otherwise, the reaction conditions appear to be very similar to those obtaining in the berginisation method. Like the latter, it is applicable not only to coal and other solid materials, but also to the treatment of tars, mineral oils, or their distillates, and even to such bodies as asphalts and resms. Presumably it is in the treatment of heavy oil distillates and residues that the Standard Oil Company is interested, for any process using coal as starting material could scarcely be an economic proposition for some years to come in the United States, considering its natural oil resources. It may be remarked that the engineering difficulties associated with the treatment of large quantities of materials under the high temperatures and pressures proposed (of the order of 500° C. and 200 atmospheres) are very considerable, even to an organisation like the IG., which has unparalleled experience of the technique of high-pressure working. Any estimation of the commercial importance of the process must therefore be reserved until it has definitely emerged from the experimental stage and more detailed information is available concerning it

It is now twenty-one years ago since the Victoria Falls and Transvaal Power Company was granted rights to utilise the Falls for the generation of electric power. Hitherto the Company has only used steam plant to produce power, and recently it has received a communication from the Northern Rhodesia Government in which stress is laid on the principle that it is not in the public interest that this source of power should remain indefinitely unused. The Company has replied that it has always been anxious to utilise the power of the Falls commercially as soon as possible. It is quite willing that the rights and conditions granted twenty-one years ago should be suitably modified or expanded, in a similar way to that adopted in other countries for the control of power undertakings. The Company was founded with the object of supplying the Transvaal gold

mines with power from the Falls. It was soon found out that owing to the heavy costs of transmission the scheme was then commercially impracticable. The company has endeavoured to find an outlet for power in Rhodesia. The vast size of the country, however, the widely scattered white population, and the fact that the Falls are situated at such a great distance from centres where there might be possibilities of export trade, present serious difficulties in the way of development. It is doubtless these difficulties that have prevented industries requiring large amounts of cheap electrical power from being attracted to the country.

In an interesting paper to the Wireless World of July 13, Captain Eckersley, the engineer to the British Broadcasting Corporation, discusses the considerations which led to the proposal to establish a new distribution of broadcasting stations in Great Britain so as to enable listeners to have the choice of alternative programmes The problem is a difficult one owing to the variations in the reception depending on the distance from the broadcasting station. If an alternative programme is provided, it must be possible for any one to switch from one to the other with great ease. It is useless to give as an alternative a programme the reception of which is distinctly inferior. The author divides the service areas round a broadcasting station into zones, which he calls the 'wipeout 'area, the A, the B, and the C service areas. The wipe-out area is bounded by the field strength contour of about 30 millivolts per metre. In this area, cutting out the local station is difficult unless very special apparatus is used. In the A area the field strength lies between 30 millivolts and 10 millivolts per metre, in the B area between 10 millivolts and 5 millivolts per metre, and in the C area between 5 millivolts and 2 5 millivolts per metre.

In an A service area defined as explained above the listener is practically certain of an uninterrupted service, and electric trains or trams or X-ray apparatus will rarely affect him. In a B service area there is good crystal reception, but in a C service area the listener is often at the mercy of outside interference. In London the 'wipe-out' area is roughly a circle of six miles radius, with its centre at the broadcasting station. The space between this and a concentric circle of about 12 miles radius is the A service area. A circle of 18 miles radius includes the B service area. and the C service area is included within a radius of 30 miles Daventry having a long wave-length attenuates much less rapidly than London. In the future, much higher aerials must be used so as to improve the efficiency of the radiation. To get an even distribution this efficiency must be improved to the utmost. By international agreement Britain has been allotted ten wave-lengths. The author considers that the best way to reframe distribution is to use for the main service fewer transmitters. He thinks that five centres of distribution, each using two wave-lengths, would be the best.

SIXTY per cent. of the total cost of farm produce is chargeable to power and labour; farmers cannot,

therefore, afford to neglect any possible means of reducing such costs. Mr. R. Borlase Matthews, in the Scottish Journal of Agriculture, vol. 10, p. 271, discusses electricity in farming and gives several striking examples of economy that can be effected by its use. He considers electricity profitable at 8d. a unit for light and 4d. for power, though in many cases, especially where manual labour is at present employed, a considerably higher rate would be found economic. Electric lighting has proved very successful in poultry houses during the winter months, 15-35 per cent. more eggs being obtained at a time when prices are highest, owing to the increased hours of feeding and exercise, bees also have been found to produce 17 lb. more honey per hive per annum when electrically lighted and heated. Electric power is particularly suited to dairy work owing to the special need for cleanliness, and when used for cream separating or other daily operations where manual labour is at present employed, the cost of installation may be recovered in twelve months. Great saving is also obtained by the use of electric milking machines.

Mr. Matthews states that hay can be artificially cured by electric power, and has a better aroma and greater nutritive value than the naturally cured pro-The hav is cut green or even wet and stacked immediately; air is then driven in through wooden ducts, the moisture and heat evolved being thereby dissipated. The curing depends on temperature control and the arresting of the process at the correct point. Electric ploughing is not yet used as much in Great Britain as on the Continent, but even at its present stage it compares favourably with all other methods of ploughing. Special types of farm buildings are not necessary before electrically operated machinery is installed; in fact electric power is being successfully used in many low buildings in Scotland. Besides the enormous commercial value of the development of electric power in farming, there would result a social service of the first importance, namely, the raising of the standard of life in rural areas

Adjoining the Brent Valley Golf Links in the Borough of Ealing is an estate of seven acres, the greater part of the grounds of which have, from being left almost entirely untouched for fifteen years or more, become a recognised haunt of birds, and many species are known to have nested there. The Selborne Society has long wished to protect the ground in question, and at last there is an opportunity of acquiring it It has been suggested that it would make a fitting memorial to the late W. H. Hudson, who helped the Selborne Society to establish the Brent Bird Sanctuary at Perivale higher up the river. Lord Montagu of Beaulieu, Lord Avebury, and Sir John Otter are making an appeal for funds to form the new bird sanctuary. Donations towards the purchase and maintenance of the property should be sent to the treasurer of the Selborne Society, Sir John Otter, at the Hermitage, Hanwell, W.7.

An esteemed contemporary, Chemistry and Industry, with enviable bonhomie, frequently looks out upon the world with a twinkle in its eye—occasionally

with juxtaposition of tongue and cheek-and sees all kinds of delightful things beyond the strict range of its title. Thirty of these glimpses (Dr. Stephen Miall calls them "Chemical Reflections") have been collected and republished by Messrs. Ernest Benn, Ltd., for the entertainment and (or) instruction of a wider circle. The author, although he denies being either a chemist or a writer, has indeed a pretty wit and a sturdy commonsense which give point to his remark (page 21) that "it costs less to read Chemistry and Industry than to take stalls to see 'No, No, Nanette.'" Thoughts on an oyster jostle with the coking of coal; holidays (two of them), science and religion in the United States, bad trade, the scope of organic chemistry, the late Labour Government, and one or two outstanding personalities are all 'reflected' as in a mirror, which, to be candid, has not always a plane surface. That, however, naturally makes the reflections all the more amusing.

Mr. H. Barkley, of the Commonwealth Weather Bureau, read a paper on "Some Correlations between Ramfall and Production in Australia," to the University of Melbourne Agricultural Society, on June 10. Mr. Barkley began with a consideration of area rainfall in Australia; he showed from observations made over a period of years the possibility of ascertaining the frequency distribution of rainfall in any district He pointed out that a calculation of the probability of rainfall in excess of a certain minimum in one year followed logically from such data; the use of such calculations made the risks of the pastoral industry ascertainable. Turning to the wheat crop, Mr. Barkley showed that in the curve of annual yields there is a steady rise, due presumably to the introduction of superior methods of cultivation, and that the mean curve can be calculated, from this curve there is an 80 per cent. correlation between August-September precipitation and final yield. Crop estimates based on this method have the great ment of being early. In the season 1926-27 they were within 10 per cent. of the yield finally reported. Rains in October and November have some influence on the yield, but chiefly in increasing grain size and water content. Dealing with the pastoral industry, Mr. Barkley showed that grazing capacity per acre is in the western half of the State correlated with rainfall, and that average fleece weight varies in conjunction with that of January and February. In the eastern half of the State, where the ramfall is considerably higher, and in the central district, where hand feeding is frequent, the results are divergent. As regards lambing, observations on certain large estates show the existence of a close correlation between the combined precipitation of January and April and lamb-production.

The full programme has now been issued of the meeting on Sept. 1-4, at Basel, of the Swiss Society of Natural Sciences. Dr. Fritz Sarasin will deliver his presidential address on Sept. 1, and special lectures will be given by Profs. A. Brachet, L. Courvoisier, L. Duparc, and H. E. Sigerist, as was announced in

our issue of June 11, p 866 The fourteen sections into which the scientific work of the meeting will be divided, together with the names of the sectional presidents, are as follows Medical biology (Prof. R Stachelin, of Basel), chemistry (Prof. H Rivier, of Neuchâtel); physics (Prof. P. Debye, of Zunch); geophysics, meteorology, and astronomy (Prof. S. Mauderli, of Bern), mathematics (Prof F. Gonseth, of Bern); pharmacy (J. Lang, of Davos); geology (Prof A. Jeannet, of Neuchâtel); mineralogy and petrography (Prof M Rheinhard, of Basel), palæontology (Dr A. Tobler, of Basel), zoology and entomology (Prof A Reichensperger, of Freiburg), general botany (Prof E Wilczek, of Lausanne); systematic botany and plant geography; anthropology and ethnology (Prof R. Zeller, of Bern), history of science and medicine (Prof G. Senn, of Basel). Excursions of special interest to geologists, petrographers, and botanists respectively have been arranged as well as numerous social functions. The chairman of the reception committee is Dr. J. Roux, Naturhistorisches Museum, Augustinergasse 2, Basel

THE third meeting, since the War, of the International Commission for the Exploration of the Upper Air is to be held at Leipzig on Aug 29-Sept. 3. The previous meetings were at Beigen in 1921 and in London in 1925. Sir Napier Shaw is president of the Commission, in succession to Prof. V. Bjerknes; the secretaries are Dr Th. Hesselbeig, director of the Meteorological Institute of Oslo, and Mr R. C K. Lempfert, assistant director of the Meteorological Office, London. The local arrangements are in the hands of Prof. Dr Weickmann of the Geophysical Institute of the University of Leipzig. The principal business of the meeting is to consider ways and means for the re-establishment of the publication of the results of the international cooperation in aerology in continuation of the agreement arrived at in St. Petersburg in 1904 which was interrupted by the War. In accordance with instructions of the Commission, a specimen volume of "Comptes rendus des jours internationaux, 1923," has been prepared, and with the aid of contributions from the Meteorological Section of the International Union of Geodesy and Geophysics, and from other sources, has been printed for circulation main features, the volume follows the precedent of the "Réseau Mondial," an annual volume of observations of pressure, temperature, and rainfall for the globe, which is published by the Meteorological Office, Air Ministry, and dates back to 1910; but the specimen volume contains two new features: first, a folio of maps of the distribution of pressure over each hemisphere on the thirty-six "international days" of 1923; and secondly, a folio of "tephigrams" or representations of the results of observations of registering balloons on the international days expressed as curves referred to absolute temperature and entropy as co-ordinates, and therefore specially expressive of the energy of dry or saturated air in the atmosphere on those days.

The Chemiker-Zeitung of June 22 contains a special supplement dealing with the progress of industrial morganic chemistry in the years 1924–1926. The review is by no means confined to progress in Germany but extends to other countries. The nitrogen problems are dealt with in very considerable detail. Then follow a lengthy account of progress in the manufacture of dyestuffs during 1926 and a report on synthetic sweetening substances during 1925–1926. The value of these reports is greatly increased by the numerous references to patent literature and to other journals.

The Report of the National Research Council of the United States for the year ending June 30, 1926, shows that the expenditure of the Council for the year was approximately a million dollars, about a third of which was disbursed for Research Fellowships. These are awarded to candidates who have gained the Ph D. degree or its equivalent and have shown marked ability in research. For the year 1925–26 the number of fellowships awarded was: in physics 26, chemistry 26, mathematics 11, medical sciences 36, anthropology 4, botany 11, zoology 11, psychology 7, seed germination 1. Others are appointed in co-operation with organisations affiliated with the Council, for research in agricultural and industrial problems. In agriculture 7 fellowships were awarded.

VOLUME 18 of Contributions from the Jefferson Physical Laboratory of Harvard University contains reprints of forty-three papers by the staff and students published during the year 1925. Seven of these relate to the effects of high pressure on viscosity, compressibility, or magnetic susceptibility, three to band spectra, ten to X-ray phenomena, three to the Hall and related effects, four are on photo-chemical problems, and several deal with the atom and its structure. About a third of these papers are due to the work of the four National Research Fellows at the Laboratory. Prof. Bridgman's paper on the effect of pressures up to 12,000 atmospheres on the viscosities of forty-three pure liquids is one of the longer papers and forms a valuable addition to the information which is being got together by the Research Committee on Lubrication of the American Society of Mechanical Engineers. A short paper describes the equipment of the Cruft High Tension Laboratory for precision X-ray research, and the volume includes obituary notices of Profs. Sabine and Trowbridge by Profs. Hall and Lyman respectively. No one with this volume before them can doubt the value of the Jefferson Laboratory as a centre for research.

Under the will of the late Thomas L. Gray, the Royal Society of Arts is residuary legatee of his estate for the purpose of founding a memorial to his father, the late Thomas Gray, who was for many years Assistant Secretary to the Board of Trade (Marine Department). The objects of the trust are "The advancement of the Science of Navigation and the scientific and educational interests of the British Mercantile Marine." The Council now offers a prize

of £100 for a valuable improvement in the science or practice of navigation proposed or invented in the years 1927 and 1928, and a prize of £50 for an essay on "The Practice of Navigation in the Mercantile Marine" The essay must be based on the actual methods used by the writer during his career, with special reference to the instruments used as aids to navigation, and the effect of stowage of cargo on the steering, speed, and safety of the vessel. Essays must be typed or clearly written and must be sent in under a motto, accompanied by a sealed envelope enclosing the author's name. Competitors must send in their essays not later than Dec. 31, 1928, addressed to the secretary of the Royal Society of Arts.

WE have received from Messrs. Brown and Son, of Alembic Works, Holloway, London, N, the fourteenth edition of their catalogue of laboratory apparatus and equipment. The greater part of the volume is devoted to apparatus suitable for industrial research laboratories and the larger technical institutes Illustrations are given of benches and other fittings supplied to the laboratories of H M. Government, the Imperial College of Science, the University of Liverpool, etc Considerable space is devoted to ovens and stills, combined or separate, suitable for large or small laboratories Electrically heated ovens, vacuum ovens, and high-pressure steam ovens, incubators heated by gas or electricity, centrifuges, explosion cupboards with sliding steel doors, electrical tube and muffle furnaces, mixing machines for stiff pastes, end-runner mills, tilting boiling-pans and cold storage chests will be found in the list. Special features are patent self-sealing autoclaves, designed to withstand pressures up to a thousand atmospheres. rectifying stills for alcohol and other liquids, with capacity ranging from five to fifty gallons, and electrically heated Soxhlet extractors for ordinary laboratory use or for quantities up to twenty gallons of solvent.

Readers interested in early maps and geographical books should see the latest catalogue (No. 498) of Mr. F. Edwards, 83A High Street, Marylebone, W 1. which gives particulars of upwards of 1200 items, some of great rarity. Reproductions of the most interesting maps are given. The catalogue will be sent free upon application

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:-Inspectors of stores for the Indian Stores Department-The Secretary to the High Commissioner for India, 42 Grosvenor Gardens, S.W.I (Aug. 22). A junior technical officer at the Royal Aircraft Establishment to assist in the experimental development of electrical equipment for use in aircraft—The Chief Superintendent, R.A.E., South Farnborough, Hants (Aug. 27, quoting A.199) An advisory agricultural economist in the University of Reading-The Registrar, The University, Reading (Aug. 27). An assistant inspector of weights and measures in the Weights and Measures Department of the City of Nottingham—The Town Clerk, The Guildhall, Nottingham (Aug. 29). A lecturer in radiology, a lecturer in anæsthetics, a demonstrator for the prosthesis room, and a demonstrator for the conservation room of the Cairo Dental School—The Director, Dental School, Ministry of Education, Cairo (Sept. 1). An assistant lecturer in mechanical engineering at the Bradford Technical College—The Principal. Technical College, Bradford (Sept. 5). An adviser in agricultural zoology and a research assistant for soil survey work in the department of agriculture of the University College of North Wales—The Secretary and Registrar, University College (Department of Agriculture), Memorial Buildings, Bangor (Sept. 10). A professor of dentistry

m the University of Otago, New Zealand—The High Commissioner for New Zealand, 415 Strand, W C 2 (Sept 15) An assistant lecturer in physics in the University of Manchester—The Registrar, The University, Manchester (Sept 20) An assistant lecturer in economics at Auckland University College, New Zealand—The High Commissioner for New Zealand, 415 Strand, W.C.2. A junior assistant physicist, under the directorate of radiological research of the Research Department, Woolwich—The Chief Superintendent, Research Department, Woolwich, S.E.18.

## Our Astronomical Column.

Conjunction of Jupiter and Uranus—These two planets reach opposition next month, and are now observable well before nudnight. They have been in south declination for many years (six and forty-two respectively) and have now returned to the equator On Aug. 19 Uranus is 49' due north of Jupiter, so it is an easy opportunity to identify the former planet It is visible to the naked eye in a clear sky with acute sight, if one knows exactly where to look.

MAXIMUM OF MIRA.—This remarkable variable star is due to attain its maximum at the end of September, as it will then be nearly opposite to the sun, the conditions for observation will be very favourable. It is already visible to the naked eye, but it is not high enough for convenient observation until after midnight. It will be interesting to compare Mira with neighbouring stars during the next few weeks, and to note its gradual increase in light. The star attains the second magnitude at some maxima, the third at others

SKY ILLUMINATION DURING THE TOTAL SOLAR ECLIPSE OF JUNE 29.—It has been observed in several eclipses that the recovery of light at the end of totality appears to be far more rapid than its decline at the beginning of it. Miss Catherine O. Stevens. writing from 3 Heron Court. Richmond, Surrey. refers to the total solar eclipse of June 29 in particular, and ascribes the effect to the fact that the shadow cone pierced the atmosphere at an angle so acute that it reached the atmosphere vertically above any locality in advance of its arrival at the place itself, and so caused a good deal of gloom before totality. Allusion has already been made to this effect in NATURE of July 9 in explanation of the fact that the descent of darkness and return of light at Colwyn Bay happened some seconds before the actual beginning and end of totality. It may also have had an effect in causing the return of light to be more rapid than its withdrawal, but in this case the effect ought to be reversed at an evening eclipse, the with-drawal being more rapid than the return. Such an effect is seldom if ever noted. It was certainly not the case at the afternoon eclipse at Algiers in 1900, but in that case the air was so transparent that atmospheric effects would be much less conspicuous.

COMETS.—No further news of Gale's comet has come to hand, and it is to be feared that the object has been lost. It is, however, possible that unreported observations have been made in the southern hemisphere.

Senhor Mello e Simas has published some researches on the conjectured identity of Comet Comas Sola with 1890 VII (Spitaler). He has carried the position of the former back to 1912, when it made a near approach to Jupiter, and finds that it was about four astronomical units from the position of the latter, brought

up from 1890, with perturbations by Jupiter up to 1901. He concludes that the two comets are not identical, but this cannot yet be considered as definite; Spitaler's comet was a difficult object in 1890, and the observations were neither numerous nor very exact. It is, therefore, quite possible that its accepted period is sufficiently in error to permit of the two comets being identical. The orbit of comet Comas Sola is much better known, since this has been well observed under favourable conditions for more than half a year; it would seem, therefore, to be the safer course to start from this end, and work back with different assumed periods, to see whether any of them would fit with Spitaler.

L'Astronomie for August contains an article by Mme. Flammarion on comet Pons-Winnecke, with reproductions of two photographs taken by M. F. Quenisset on June 23. The comet appears as a large nebulosity, some 25' in diameter, slightly extended to the north, that is, towards the sun The nucleus was of mag. 9. On June 26-27 a tail 1° long — was photographed, in P.A. 230°. The comet was easily visible to the naked eye as a small white transparent cloud, not unlike the Andromeda nebula.

Dr. G. Merton has obtained the following photographic observation of comet Grigg-Skjellerup

July 5 96768 U.T., R A. (1927 0) 17<sup>h</sup> 19<sup>m</sup> 38 76<sup>s</sup>, N. Decl. 39° 36′ 27·5″.

The comet will be low in the north-east just before dawn. It is very desirable to find the comet this year, as the circumstances will be more unfavourable for observation at the next return in 1935.

### Research Items.

EARLY MAN IN AMERICA —In the Scientific American for August, Mr. Harold J. Cook returns once more to the question of the antiquity of man in America. He recapitulates the circumstances of the discovery of the Nebraska tooth in the tertiary deposits of the divide between the North Platte and Niobrara Rivers near the Agate Spring Fossil Quarries These deposits were discovered by the writer and Dr. W. D. Matthew in 1908 and have proved rich in mammalian remains of tertiary age, some showing distinct relationship with Asiatic forms Fresh discoveries were made year by year until the owner of the land ordered the work to stop. Work by Mr. Albert Thompson, of the American Museum of Natural History, on an adjacent ranch produced from among the remains of a characteristic phocene fauna evidences of human culture in the form of artefacts of green bone of contemporary animals implements some are drilled, many shaped or shaipened in various forms, while others have been used for pounding. Such is the result of a preliminary critical study by Prof. Fairfield Osborn and Mr Thompson. The resemblance of these implements to those of modern Indian workmanship has already been pointed out. In January last investigations were begun on a site farther south at Frederick, Oklahoma, on a ridge of sand and gravels lying on the eroded surface of Permian Period Red Beds. The geological evidence shows that the top of the highest hill in this area was once the bed of a river. It is now one hundred feet above valley level and two hundred and eighty feet above the present Red River. Three periods of deposition on the old Red Bed floor are shown. In Bed A, associated with typical pleistocene animal remains were stone implements made by man, showing a degree of culture comparable with that of the modern Indian nomads of the plains. This evidence would, therefore, support the view that the Indian has changed little over a very long period of time, and meet the arguments of those who refuse a high antiquity to the Indian on account of the modern character of the remains, skeletal or other. discovery is dated tentatively at a period of 365,000 years ago and affords the most conclusive evidence of Glacial Age man yet found in America.

CANCER AND ITS TREATMENT.—The Irish Radium Committee has issued its Report, compiled by Dr. Walter Stevenson and Mr. Maurice Hayes, on the treatment of cases of cancer by means of radium and radium emanation during the year 1926. A large proportion of the cases was unfortunately at an advanced stage and a palliative effect only could be hoped for: in this respect the treatment is attended with considerable success In a small number of cases, with or without operation, the treatment has apparently effected a cure. Rodent ulcer is particularly amenable, and certain non-cancerous conditions, such as ulcers, local sepsis, sciatica and others, were much benefited (Sc Proc. Roy. Dublin Soc.. vol. 18, No. 39, 1927, p. 443). The Ministry of Health has issued a Report by Dr. Janet Lane-Claypon on a statistical inquiry into the results of treatment of cancer of the uterus (Reports on Pub. Health and Med. Subjects, No. 40). The Report is based on the examination of data published prior to March 1926, contained in 848 articles derived from sixteen different countries and dealing with some 80,000 cases of the disease. The principal findings are (1) that patients do not seek advice until an average period of 6-9 months has elapsed after the first occurrence of symptoms, (2) that rather less than half the patients who then apply for treatment are at a stage at which effective operation is practicable, (3) that the results of operation at an early stage of the disease are roughly twice as good as those in patients whose disease is still practicable for operation but who apply late, and (4) that cancer of the cervix is not more serious in younger than in older women.

MINERS' AND QUARRYMEN'S PHTHISIS.—Inhalation of dust containing sharp particles of silica or quartz induces in those subjected to it either a condition of fibrosis of the lungs or the same condition complicated with tuberculous infection—the true miners' phthisis. The last-named variety in the Rand mines has been the subject of a study by Mr. Mayrogordato Down to 1905 the dust particles in the air of the mines averaged 150 mgm. per cubic metre of air, with a phthisis incidence of 30 per cent. Since then, by the compulsory use of certain measures, the dust particles were reduced to 20 mgm. in 1911, to 5 mgm. in 1913, and to 2 mgm. in 1921, with a fall in the phthisis incidence to 14 per cent. in 1915, 10 per cent. in 1916, and 3 per cent. since 1921 (Publications of the S. African Institute for Med Research, No. 19, 1926). A similar effect from the inhalation of quartz particles derived from slate dust is apparently seen in the high incidence of phthisis among the slate workers in the Gwyrfai of phthisis among the state workers in the Computation of a Report by Dr. T. W. Wade to the Ministry of Health (Reports on Pub. Health and Med. Subjects, No. 38, 1927). The phthisis death-rate among the slate quarrymen and workers of Gwyrfai reaches a maximum at about sixty years of age, being then about \$2 per 1000 whereas the general death-rate for males. 8 per 1000, whereas the general death-rate for males from phthisss in England and Wales at that age is only about 1.25 per 1000. Males other than slate workers of Gwyrfai of the same age have a phthisis death-rate only a trifle more than that for England and Wales.

MIGRATION IN APHIDES.—In Science Progress for April and July, Dr. J. Davidson, of the Rothamsted Experimental Station, discusses the biological and ecological aspects of migration in aphides. True aphides of the family Aphididæ (as distinct from the Phylloxeridæ) may be separated into non-migrating species, whose whole life-cycle is spent upon one type of plant, and migrating species. In the latter case one portion of the life-cycle occurs on one type of plant (primary host) on which the fertilised eggs are laid, while the remainder of the life-cycle consists only of parthenogenetic generations which occur in association with other types of plants (intermediate hosts). The primary hosts are trees or shrubs, while the intermediate hosts may be herbaceous plants or other trees and shrubs. The complete life-cycle is practically confined to species occurring in temperate climates. In warmer countries such as Formosa, Java, and the southern United States the sexual phase is frequently suppressed, and continuous parthenogenetic reproduction is the rule. The migrating habit seems to have developed in relation with changes in the world's flora. Those species which are primarily non-migrating, such as members of the tribes Lachnini and Callipterini, exhibit certain primitive characters. The migrating species, on the other hand, exhibit varying degrees of specialisation in habit and form correlated with the extent to which the migratory habit has developed. In general, those species associated with herbaceous plants represent the most recent development in aphid evolution.

THE CONTROL OF THE TSETSE-FLY -In the Bulletin of Entomological Research for June 1927, Drs. Ll. Lloyd, W. B. Johnson, and P. H. Rawson have an important paper dealing with experiments in the control of the Tsetse-fly in Northein Nigeria An interesting experiment was carried out in which wild game was excluded from a good secondary focus of Tsetse-fly by means of a strong fence. This set up a state of starvation in the case of the species moi sitans and to some extent in tachinoides There was marked reduction in abundance of both species of the Tsetse, especially of *morsitans*. It is considered that game destruction, if it could be effectually accomplished, would lead to the disappearance of the latter species, but not tachinoides. It is for this reason that a policy of game destruction is not recommended; it is suggested, on the other hand, that a policy of laissezfaire towards the game in Northern Nigeria so that the increase of wild Ungulata is checked, would tend to restrain the increase and spread of the Tsetse. A successful experiment in deferred grass burning is described. The late sweeping fire was found to result m a great mortality of the flies and their pupæ in both the species of Tsetse It scarcely affected the growth of established thicket, but probably checked the expansion of such and the formation of new thicket. It is considered that late grass burning, well organised, might have a good effect in Tsetse reduction in Northern Nigeria, but there are great difficulties involved.

Animal Life in Hot Springs —Prot. C. 7. Brues has summarised (Quart. Review of Biology, vol. 2, No. 2, 1927) the main facts relating to animal life in hot springs. Thermal waters contain only a small amount of dissolved oxygen and they are often impregnated with salts in solution, usually either calcium carbonate or silica. Compared with plants, animals have considerably less power of adjustment to high temperatures, and even the most resistant forms of animal life are unable to endure the degree of heat at which certain plants thrive Of the insects which occur in hot springs the author refers to beetles, some of which have been reported from water at 115° F., and to the larvæ of Chironomus, which he found abundant in the mud of a shallow thermal pool at a temperature of 120° F. in Yellowstone Park. A few Crustacea have adopted a thermal habitat, e.g. species of Gammarus and of Cyclops and an isopod (Exosphæroma). This last is especially interesting, because a closely related extinct genus is preserved in hot spring deposits of lower Oligocene age, indicating a long thermal ancestry. Molluscs such as Physa and Limnæa are also known to mhabit hot springs. Tadpoles of a frog were found in Yellowstone Park in water at a temperature of 104°-106° F., that is, several degrees above the temperature at which unacclimatised tadpoles of the frog and the toad die.

Plankton Production.—There is an obvious need for some quick method of estimating the production of plankton in the sea to supplant the present laborious process of counting the diatoms themselves. It seems possible that such a method may be found in a study of the oxygen content of sea-water and its relation to the photosynthesis of the diatoms present. To this end preliminary observations were carried out by T. Gaarder and H. H. Gran in an investigation of the production of plankton in the Oslo Fjord in 1916 and 1917 (Cons. Internat. Rap. et Proc. Verb., 42, 1927). Hydrographic and plankton observations were made, and at the same time, by suspending flasks of sea water with its contained plankton at different depths, artificial cultural experiments were set up. Results obtained in the open waters could not be regarded as

conclusive on account of the constant changing of the water masses in the fjord brought about by currents. In the flasks the greatest reproduction among the diatoms in March took place at 2 m. and 5 m., and there was still sufficient increase at 10 m for the oxygen output to balance the uptake through respiration. In March the necessary nutritive substances occurred in the sea water in sufficient quantities in proportion to the consumption by the diatoms, but in September they were insufficient to produce a profuse development of diatoms. Addition of phosphates and nutrates to the water in the flasks in September caused a rapid production of 100,000 cells per litre in 3 days.

Plant Chimæras. — Numerous chimæras have been produced by Messrs Jorgensen and Crane (Jour. Genetics, vol. 18, No 2) in Solanum, using the well-known methods of Winkler. The species grafted together were S. lycopersicum, S sisymbrifolium, S. luteum, S. nigrum, and S. guineense species have different multiples of twelve chromosomes, as Winkler originally showed for some of them, so that the parental tissues can be identified in the chimera by means of the dividing cells. A new result is the discovery that in many forms, which were regarded as sectorial chimæras only, the superficial layers of a sector belonged to the other species. Such forms are really incomplete periclinals, and it is proposed to call them mericlinals. The morphology of the various chimæras is described, and it is shown that the periclinals generally show somatic instability, reverting to the pure form which forms the core. In one case, however, in S. lycopersicum-lutcum, in which there were probably three or four outer layers of luteum, reversion took place through transitional stages to the pure luteum.

CHROMOSOME ATTRACTIONS IN PLANTS.—The arrangements of the chromosomes at reduction have been studied by Dr. Belling (Jour. Genetics, vol. 18, No. 2) in Datura and other plants, especially in triploid, trisomic, and haploid plants. In haploid individuals the chromosomes show no mutual attractions. In diploids, corresponding ends of chromosomes attract each other, while the two ends of the same chromosome show different attractions. Long chromosomes may also show attractions at other points. From a study of triploids in which trivalent chromosomes are formed, the three members show the five expected arrangements. The fact that the triangle configuration does not normally occur indicates that the attractions of the two ends of a chromosome are different. On this hypothesis, eight configurations would be expected in totraploids and they have been found. The trisomic (2n+1) mutations of Datura give rise to certain secondary forms in which one of the chromosomes of the trivalent has the same attraction at both ends and consequently forms a small circlet. It is suggested that this has arisen through crossing-over in the middle between two homologous chromosomes lying parallel but with reversed orientation. There is also a suggestion of crossing-over between non-homologous chromosomes, producing an isomorphic strain which in crosses combines to form a ring of four chromosomes. These are further steps in showing that genetical variations have a cytological foundation.

TERTIARY CEPHALOPODA FROM JAPAN.—Cephalopod remains are rare in the Tertiary rocks of Japan, only three species having hitherto been described. Two new forms, Aturia aturi, var. tokunagar, and Nautilus (s s) japonicus, are now added to the list by S Shimizu, whilst a species hitherto identified with Aturia zigzag has been given separate rank as A. yokoyamar by

T Nagao (Science Repts., Tôhoku Imp. Univ., Sendai, Ser. 2, vol 9, No. 2). Excellent plates accompany both papers

INDIAN TERTIARY MOLLUSCA.-In 1909 the first part of Cossmann and Pissarro's work on the Mollusca of the Ranskot Series, comprising the Cephalopoda and Gastropoda, was published in the *Palæontologia Indica* (New Series, vol. 3, pt. 1). The second pointion on the Brachiopoda and Lamellibranchiata (with some species from the Cardita beaumonti beds) has now, after many vicissitudes, been issued (Pal Ind., New Ser. vol. 6, mem 2) A translation was made by the late Dr E Viedenburg from the original French and the two MSS sent to M Cossmann tor revision in 1915, but were lost without trace, probably sunk with other mails Fortunately a duplicate translation was found among Dr. Vredenburgs literary remains, and from that the present part has been prepared One brachiopod and twenty-five lamellibranchs, nine of which belong to the Cretaceous Cardita beaumonti beds, are described, including eighteen believed to be new species, and figured on four plates.

OIL IN AUSTRALIA —The vexed question of petroleum in Australia is once again mooted by the appearance of another report, this time dealing with portions of the Kimberley Division of West Australia, with special reference to the possible occurrence of mineral oil in the Fitzroy Basin, and written by Mr. T. Blatchford, Assistant State Mining Engineer. While we have nothing but praise for the painstaking efforts and perseverance of the many experts in their search for petroleum in this continent, the prospect of ultimate location of commercial oil-pools, especially in the West, seems mevitably slight, if on first principles alone, and a perusal of this report of another possible area does not incline one to a change of opinion. In the present instance the most likely beds would seem to be those of Cambrian age, with which some discovered bitumen outcrops are apparently connected, more particularly the Upper Cambrian beds overlying basalt flows. The author states that suitable structures exist in the area, and other conditions are tavourable, though proving the presence of oil will necessitate boring probably to 4000 or 5000 feet. Two trial borings through similar rocks in a contiguous district, at Mt. Wynne and the Ord River Basin, were unsuccessful, the Mt. Wynne boring being abandoned at 2400 feet without meeting oil-bearing beds, the Ord River bore being shut down in basalt.

PHOTOMETRIC MEASUREMENTS DURING THE TOTAL Solar Eclipse of June 29.—During the total solar echpse on June 29, Mr. J. S Dow made many photometric observations of the total illumination Although he was not quite in the centre of the belt of totality, he was favourably situated to observe the phenomena. He had previously made photometric observations of the partial eclipse of 1912 under excellent weather conditions and so knew exactly what to expect. He publishes his results in the Illuminating Engineer for August When he began his observations about 5 20 A.M. the sky was clearing of clouds. This led to an actual increase in illumination notwithstanding that the eclipse had begun At 6.10 the sun emerged from the cloud as a watery crescent, but it disappeared again just before totality and did not appear again until totality was over At totality the illumination fell with great rapidity for a few seconds and then rose with equal rapidity The lowest illumination recorded was about half a a foot candle. It then rapidly rose to more than 2000 foot candles, due partly to the passing of the eclipse

and the fact that the altitude of the sun was increasing. Owing to the clouds it was impossible to forecast accurately what the illumination would be, but the agreement between calculated and observed values in the 1912 echipse was excellent. Apparently values of the illumination so low as a fiftieth of a candle foot were obtained by an observer at Southport. It is practically impossible at present to predetermine the illumination resulting from a total echipse. It would be necessary to have accurate data of the candle power of the corona. Quite apart from the interference of clouds, the illumination probably varies with the width of the band of totality and the position of the observer on it.

A NEW SOURCE OF ARSENIC.—A paper has been published by R E Remington in the Journal of the American Chemical Society for June directing attention to a hitherto unsuspected source of aisenic in the human body. The author has examined a large number of brands of smoking and plug tobacco by means of the micro-Marsh method, and has found amounts varying from six to thirty parts per inillion These are many times in excess of the quantities permitted in foods. Nearly half of the arsenic in smoking tobacco is evolved in the smoke and about half of the arsenic in plug tobacco is soluble in water. The results show very clearly that a considerable part of the arsenic in tobacco may find its way into the body, and experiments are now being carried out to test this possibility conclusively.

THE PASSIVITY OF METALS —The unusual properties of iron and other metals which have been rendered passive by oxidising treatment have been attributed by many investigators to a protective film of oxide or other material. This explanation has been rejected by some chemists, since no film is usually visible, while iron which has been covered with a visible film by heating is often not passive. The presence of very thin films, too thin to give interference tints, has been proved by the work of U R. Evans, which has been published in the May issue of the Journal of the Chemical Society. He has found it possible to render these films visible by dissolving away the metal below them by anodic treatment or by means of iodine. The envelope of the iron electrode after anodic treatment consisted of two thin transparent parallel membranes of ferric oxide united at the two edges. There seems to be little doubt that this film is the cause of passivity; where the film is broken or contains cracks the metal is active.

Fog Production on the Neutralisation of HALOGEN HALIDES.—It has been noticed that when a current of air containing phosgene or phosphorus oxychloride is passed through charcoal and aqueous alcoholic potash, a fog develops in the vessel containing the alkali as soon as the charcoal is saturated. H. O. Askew has shown that both hydrochloric and hydrobromic acid vapours when passed into various alkaline solutions are capable of producing similar effects, more especially in the presence of colloids and dyes. A complete investigation of this subject is described in the *Journal of the Chemical Society* for May. It has been found that the relation between the amount of fog produced and the alkalı concentration, and also the amount of fog and the concentrations of the added active materials, are of the same form as the adsorption isotherm. The concentration of the acid in the fog particles and the water vapour pressure are constant and independent of the amount of fog formed, but the sizes of the particles decrease as the fogs become denser. The particles appear to have no electrical charges.

## The Leeds Meeting of the British Association.

PROGRAMMES OF SECTIONS.

THE arrangements for the ninety-seventh annual meeting of the British Association are now assuming final form, and the Local Committee at Leeds is confident that the meeting will be a success. Members are assured of a cordial welcome both from the City of Leeds and the University, and the programme of entertainments outside the Section rooms is an attractive one. The Lord Mayor and the University are giving receptions, garden parties are arranged; while for those who take more vigorous amusement a dance will be held On the evening of Sunday, Sept. 4, the Leeds Choral Union will give a concert in the Town Hall, to which all members are invited. The programme includes: Pianotorte Concerto (Grieg), "The Dream of Gerontius" (Elgar).

In the Crypt of the Town Hall there is to be an exhibition of scientific instruments and apparatus; while near the Reception Room the Meteorological Department of the Air Ministry will have an office for weather forecast work The B.B.C. is demonstrating the educational possibilities of wireless; and Mr. J. L. Baird, of the Baird Television Company, is undertaking to demonstrate television between London and Leeds during the latter part of the meeting, whilst during the first three days he will give demonstrations of nocto-vision and members will have the opportunity

of seeing a phonoscope.

Though a large industrial city with a 'smoke' problem, Leeds is a splendid centre for excursionists; and in order to meet their requirements the Local Excursions Committee has arranged a large number of attractive visits led by experts to the neighbouring country. The handbook of excursions, to be issued to each member, will be a book of permanent value to those who are interested in the district around Leeds. We have already mentioned that, thanks to the kindly offices of the Yorkshire Ramblers' Club, a number of members will be able to make the descent into Gaping Ghyll, and this will certainly be a very unusual excursion of any British Association meeting. Another excursion novelty is that to Doncaster to witness the 'St. Leger' as the guests of the Doncaster Corporation. York and Harrogate have also made preparation for the visit of a number of members; works and factories have extended invitations to members to make inspectional visits; and a number of descents into coal mines are planned. Those interested in art should not miss the opportunity of seeing the fine collection of Turners at Farnley Hall. A number of sectional excursions has also been arranged.

The list of foreign guests attending the Leeds meeting includes the following: in the department of the mathematical and physical sciences, Prof. Robert A. Millikan (Pasadena, California), Prof Peter Debye (Zurich), Dr. W. Kolhorster (Charlottenburg), Dr. W. Heisenberg (Copenhagen): in chemistry, Prof. Dr. H. Freundlich (Berlin); in zoology, Dr. S. Kopeé (Poland); in economics, Prof. J. Schumpeter (Bonn); in botany, Prof. Nils E. Svedelius (Upsala), Prof. Dr. E. von Brücke (Innsbruck), Dr. John P. Lotsy (Velp, Holland); geology, Prof. G. Delépine (Lılle), Prof. G. A. F. Molengraaf (Holland).

## SECTION A (MATHEMATICAL AND PHYSICAL SCIENCES).

UNDER the presidency of Prof. E. T. Whittaker, an exceptionally interesting programme has been arranged in Section A (Mathematical and Physical Sciences). Prof. Millikan is speaking on the spectra of the ele-

ments of the first row of the Periodic Table, and is also giving an evening lecture to the Association on cosmic rays Dr. Kolhorster will also speak on the latter subject in the sectional meeting A paper by Dr. Heisenberg on recent progress in quantum mechanics will be followed by a discussion in which Mr. R. H. Fowler and other English workers will take part. Members will also have the opportunity of hearing Prof Debye speak on the polar properties of molecules

Prof. Whiddington is to give an afternoon lecture on the luminous discharge in rare gases, which will include experiments illustrating his own researches, while the papers to be given by Dr. Aston and Prof.

Barkla are of special interest at the present time.

The joint discussion with Section B (Chemistry) on the structure and nature of colloidal particles will be o<sub>L</sub>ened by Sir William Bragg. There will also be several subsectional meetings. In mathematics a paper by Prof Turnbull on non-commutative algebra will serve as a useful introduction to the discussion on quantum mechanics, and, in addition to papers by Profs. Milne and Brodetsky, a morning will be devoted to contributions on the theory of numbers.

## SECTION B (CHEMISTRY).

THE main activities of Section B (Chemistry) will be devoted to three discussions On Thursday, Sept. 1, the president, Dr. N. V. Sidgwick, instead of On Thursday, Sept. formally reading his address, will open a discussion on "Co-ordination Compounds" Dr. Sidgwick is a recognised authority on this subject, which now occupies an important place in our knowledge of theconstitution of chemical compounds. Prof. G. T. Morgan and Dr. S. Sugden, who have made important contributions to the subject, will be amongst those taking part. The joint discussion with Section A on "The Structure and Formation of Colloidal Particles" on the following day should prove particularly interesting. Sir William Bragg, Prof. H. Freundlich of the Kaiser-Wilhelm Institut, and Prof. R W. Whytlaw-Gray are taking part. Prof. G. Barger will open the discussion on Sept. 5 on "The Chemistry of the Hormones." Profs. H. S. Raper, J. Mellanby, J. C. Drummond, and E. C. Dodds will also discuss these substances, the knowledge of which has recently been greatly extended by the elucidation of the chemical constitution of thyroxin and recent extensive researches in physiology and biochemistry. The morning of Sept. 6 will be devoted to the reading of miscellaneous papers, when Profs. H M. Dawson, John Read, and others will describe progress made in recent investigations. Throughout the meeting, excursions of special chemical interest have been arranged through the kind co-operation of a number of chemical manufacturers and research associations m and near Leeds.

## SECTION C (GEOLOGY).

THE country round Leeds is of special interest at the moment to the geologist conversant with rocks of Carboniferous age, but these rocks and the problems associated with them do not absorb all the attention of Section C. The programme of the Section is a full one; full not only of topics for discussion in the meeting room, but also of visits to places of interest in the neighbourhood where certain of these topics may be further considered in the field. Every branch of the subject is represented in the programme—physical and stratigraphical geology, palæontology, and petrology—while within the purview of each there are papers of interest to the general reader and others which will be of greater moment to the specialist. Several of these latter communications may also have an economic value in the coalfields and in the exploration for metallic cres.

The geologist, however, considers the conditions in past times as well as those at present existing, and opportunities for speculations of this character are supplied by various authors of papers. It were perhaps invidious to select any papers for special mention, but one such discussion of a general nature may be indicated—climates of the past. The subject is by no means novel at British Association meetings, but it is one which may be studied at intervals with profit. Recent researches in geophysics, meteorology, geology, and biology have shed new light on the matter, and an examination of this new evidence should be very helpful at the moment. The relative values of these discoveries may be more easily ascertained in the course of such a discussion than would be possible in other circumstances.

Reference has been made to field excursions. These will take place each afternoon, and in addition two whole-day excursions to cover a wider range of country are arranged for the week-end included in the period of the Leeds meeting The field expeditions form a most important part of the programme of Section C, as they provide opportunity for more intimate discussion than does the lecture room. They also afford greater chances for the junior workers to meet with the more senior people and enable difficulties to be voiced which the greater and wider experience of the senior workers may help to dissipate. In this connexion it will be well to note that the numbers attending these excursions are to be limited in most cases, and a ballot for places may be necessary Early application to the secretaries is therefore advisable.

### SECTION E (GEOGRAPHY).

Polar regions have of recent years assumed a special significance in various fields of earth science. In geophysics and biology, the lands and waters of high latitudes have, by reason of their position, an importance which justifies extended research in these still somewhat maccessible areas. Problems of polar geography form the theme of the presidential address by Dr. R. N. Rudmose Brown, whilst special papers on Greenland and Iceland deal with physical conditions in relation to settlement and development.

Each year brings new evidence of man's triumph over Nature, or rather of man's increasing use of applied science for the extended exploitation of the resources of Nature. The reclamation of the Zuder Zee, which Dr. Jansma will discuss, is outstanding in this respect, whilst even the remarkable physiographic teature of the Great Barrier Reef, the subject of a paper by Sir Matthew Nathan, may one day have an economic value.

The trend of much geographical research in Great Britam has been steadily in the direction of regional interpretation. This finds expression not only in the series of papers on the Leeds region contributed by Dr. C. B. Fawcett and his school, but also in a number of detailed studies of village communities in the Channel Islands, in the mid-Trent valley and in Yorkshire. Physiographic influences, even where they no longer operate, have often left an abiding impress. It is well, however, that other factors contributing to regional definition should occasionally be thrown into strong light, and this is suggested in a paper by Dr. Vaughan Cornish, in which he dis-

cusses the fixation of linguistic boundaries by national adoption of Christianity during the Middle Ages.

#### SECTION G (ENGINEERING)

The presidential address to be given by Sir J B. Henderson to Section G (Engineering) will deal with invention and its dependence upon science. The remainder of the sectional programme includes a variety of subjects of scientific and engineering interest. Dr. T. Stanton and Sir W. B. Hardy are to introduce the subject of lubrication, a topic of great scientific and practical importance. Dr. Lander, Prof. Cobb. and Prof. Wheeler will read papers on various aspects of the coal supplies of Great Britain and their utilisation, a discussion will follow, and it is expected that a number of speakers will contribute interesting matter. This discussion will be followed by a paper describing attempts to utilise the internal heat of the earth for power production

One morning session is to be devoted entirely to papers dealing with the science and practice of electrical engineering. The important questions of supertension cables and switchgear for the transmission and control of large powers are to be discussed: the new jet wave rectifier for the conversion of A C. into D C. by means of a jet of mercury, and particulars of a large-scale plant at present in operation, will be described. A new voltage regulator, in which a valve is used to control the voltage of a D.C. generator supplying current to a laboratory, is to be described, the subject of metallic filament lamps and certain researches in connexion with them will be discussed

Papers dealing with the limits of efficiency of internal combustion engines, the transmission of power by belts, a new type of pump and with many other civil engineering problems are promised. Excursions to engineering works of various kinds in the neighbourhood of Leeds have been arranged.

### SECTION H (ANTHROPOLOGY).

Section H (Anthropology) presents a list of papers which, if not so full as usual, is not less varied. In physical anthropology several communications are of interest to educationists and those in charge of the physical culture of children of school age as well as to anthropologists: Dr. A. H. Mumford will deal with anthropometric observations in relation to school progress; Dr. R. A. Fisher's study of triplets, an investigation undertaken with the assistance of funds provided by the Association, breaks new ground and incidentally brings out deficiencies in our knowledge of the physical characters of the normal child population: and Miss McInnes' ethnological survey of Sheffield and the surrounding districts is based to a great extent on observations of school children and serves to confirm and extend our previous knowledge of the population of Yorkshire. Prof. T. H. Bryce will describe skeletal remains of Viking age from Caithness. An attempt at correlating racial, social, and religious factors will be made by Mr. J. E. Daniels in a communication dealing with Wales. Sir W. Boyd Dawkins will carry further his study of early man and his precursors in the Tertiary

A meeting in the north of England affords an exceptionally favourable opportunity for a survey of recent progress in research in the Roman period. In this field communications dealing with Scarborough, York, and Cawthorn will be received from Messrs. Collingwood, Miller, and Richmond. Dr. Oswald will give an account of his excavations at the Roman Camp of Margidunum on the Fosse Way. A second paper by Prof. T. H. Bryce will discuss the

theory of 'Archaic culture' in relation to Scotland Mrs Cunnington will describe the unique type of prehistoric monument to which she has given the name 'Woodhenge,' and Dr Clay will discuss the evidence for the overlap or the Bronze into the Iron Age in Britain. Messis, Tratman and Taylor will describe the archæology of the Mendips and the Wye valley respectively as the result of excavations carried out by members of the Spelæological Society of the University of Bristol. Dr. T. Ashby supplements the conclusions of his presidential address of two years ago by further evidence relating to the Roman system of communications in the Valley of the Tiber.

278

An important and, it is hoped, fruitful discussion will be opened by Dr. H. Frankfort dealing with the question of the early prehistoric painted pottery of the Near and Middle East, which has been found to have a wide distribution in very early times. Of a number of papers in ethnography, mention can be made only of Dr. J. H. Hutton's illuminating study of the significance of head-hunting in the Naga Hills and Mr. G. R. Carline's communication on "Primitive Looms." This latter paper is preparatory to an inspection of the collection of looms at the Bankfield Museum, Halifax, which the members will visit on the afternoon of the same day, at the invitation of the Museum Committee.

## SECTION I (PHYSIOLOGY).

Dr. C. G. Douglas is devoting his presidential address to 'The Development of Human Physiology." For too long the eyes of the experimentalist have been fixed on the 'laboratory animal'-usually the frog-while the clinician has become more and more impatient of the scanty and academical 'truths' offered to him by his laboratory colleague. recent times, however, it has become the practice of certain medical schools and research departments to use man himself as the subject of observation and experiment. The apparatus involved tends to be more costly, the technique is frequently more difficult, but the results amply justify the trouble involved

Prof. H. S. Raper's contribution is especially welcome, in that it promises a simplification of the current views about oxydases. It seems that the time is passing at which a new oxidation is satisfactorily

explained by postulating a new enzyme. There will be presented to the Section the report of

the committee appointed last year to consider particularly the classification of colour-blindness. The signatories comprise Sir Charles Sherrington, Prof. H. E. Roaf, Dr. Edridge-Green, and Dr. Mary There can be no doubt that agreement about terminology is necessary for progress in this matter, and it is to be hoped that the suggestions of this committee will meet with wide acceptance. Other contributions of interest include papers by Dr. W. Cramer on the available supply of vitamin A in relation to the demand, by Prof. J. C. Drummond on the vitamins of yeast, and by Prof. R. J. S. McDowall on the physical concomitants of mental stress, while there is to be a discussion on the circulation rate, with particular reference to its measurement in man.

## SECTION J (PSYCHOLOGY).

The programme of Section J (Psychology) is almost equally divided between topics of general interest and those of obvious practical significance, medical, educational, and industrial. Dr. William Brown's presidential address on "Mental Unity and Mental Dissociation" will probably reflect his own philosophical, psychological, and medical interests. Dr.

T W Mitchell, the editor of the British Journal of Medical Psychology and a prominent figure in the Society for Psychical Research, will contribute a paper on "Phenomena of Mediumistic Trance

Two joint discussions have been arranged, one with Section F (Economics) on "Innate Differences and — Social Status," the other with Section L (Education) on "The Psychology of Special Scholastic Disabilities" Among the papers of educational interest is one by Prof. C. W Valentine on "The Comparative Reliability of Intuitive Judgments in Men and Women," and another by Dr L Wynn-Jones on 'Children's Appreciation of Wit." Representatives of the Industrial Fatigue Research Board and of the National Institute of Industrial Psychology will speak on "Time and Motion Study," "Certain Aspects of Accident Causation," and other psychological topics of industrial importance.

We regret to record the death of Di. Henry Rutgers Marshall of New York, the well-known author of "Pain, Pleasure, and Esthetics," who had accepted the Council's invitation to attend the meeting as a distinguished guest. The abstract of the paper he intended to read on "Self-consciousness and the Selt" will be printed in the Journal and Annual Report and read by his friend Dr. C. S. Myers.

The Section has accepted a condial invitation from Messrs Rowntree and Co. of York to visit their works on Tuesday afternoon, Sept. 6, for the purpose of seeing their methods of selecting and training their workers

#### SECTION L (EDUCATIONAL SCIENCE).

MEETINGS of the Educational Science Section will be held at the Albert Hall on Sept 1, 2, 5, and 6, under the presidency of Her Grace the Duchess of Atholl, M.P. The president will give her address on Friday, Sept 2, at 12 noon, on "The Broadenme of the Outlook in Education," a subject which will no doubt attract a large audience On the same day, at 10 AM, a discussion on "Education in Tropical Africa" will be opened by Sir Theodore Morison with a paper entitled "An Educational Policy for Tropical Africa." Other papers will be contributed by Mr. Rivers Smith ("Education of the African Chief"), Mr Norman Young, Major A G. Church, and Miss S Burstall.

On Thursday, Sept. 1, there will be a joint discussion with the Psychology Section on "The Psychology of Special Scholastic Disabilities" Miss G Hume, Miss I Wheeler, and Miss A H. McAllister will contribute papers on reading, anthmetic, and special disabilities respectively, and an open discussion will follow.

A full session will be given to the subject of "Educational Need of Industry" on the morning of Sept. 5. Mr. J. Wickam Murray will open with a paper on "New Outlooks"; Mr E. Walls will deal directly with the "Educational Requirements of Industry" and Mr. J. H. Everett, Dr. H. Schofield, and Mr. A. P. M. Fleming will discuss "Facilities offered by Technical Colleges," "Engineering Training," and "Non-conventional Types of Education in Industry

respectively. "School Examinations," a subject of much discussion at the present time, will be considered on the morning of Sept. 6. Dr. P B. Ballard, Dr. J. M. Crofts, Mr. B. C. Wallis, and Mr. J. H. Arnold will contribute papers from different points of view, and an open discussion will follow. In the afternoon of Monday, Sept. 5, Sir Henry Hadow will preside at a demonstration of the work of the Leeds Schools Music and Drama League. He will open with a short address and an interesting programme will follow.

## Tidal Predictions by Mariners.1

THE publication of the fourth edition of Part 2 of the Admiralty Tide Tables may well be regarded as a memorable event in the history of practical aids to navigation. The first edition was published in 1858, reprinted annually with amendments and additions until 1909, and subsequent editions were published in 1910 and 1920. Though each edition was an improvement on that which preceded it, the type of information and the method of using it remained in all essentials unchanged. The tidal data were presented in the form associated with the names of Whewell and Lubbock, who were mainly familiar with the comparatively simple types of tide experienced in British waters.

Up to a point, it was sufficiently accurate to state that the high water follows the moon's transit by an interval which is approximately a constant at a given place Such constants have hitherto been the chief aid to navigation in ports for which no daily tidal predictions are available. In many instances it was possible to supplement this method by the use of 'tidal differences'; thus if daily predictions were available at a 'standard port,' then small corrections on time and height could be applied to give fairly good approximations to tidal movements at a neighbouring subsidiary port. It the tidal height at a given hour of the day was required, then tables and diagrams were used, the arguments being (1) the time interval between that hour and the time of high water, (2) the range of tide

The latest edition supplements this information by the harmonic constants of the principal tidal constituents for about a thousand ports, and very strong reasons are given for the use of these constants. It is even indicated that the non-harmonic constants will ultimately be omitted, and mariners are therefore advised to become familiar with the new methods. It remains to be seen whether the process of conversion will be easy, as mariners do not take kindly to new

ways of doing things

The reasons given for the change are of course entirely connected with the degree of accuracy required. The tidal oscillation is composed of a very large number of constituents which may be broadly divided into two main groups, semidiurnal constituents The non-harmonic tidal and durinal constituents constants and the tidal differences can only be functions of either the semiduirnal constituents or of the diurnal constituents It is not possible to include both diurnal and semidiumal constituents in the same constant or difference, and the constants hitherto

<sup>1</sup> "The Admiralty Tide Tables" Part <sup>2</sup> Fourth edition, 1927, containing Non-Harmonic Tidal Constants, Tidal Differences and Harmonic Tidal Constants for the Principal Ports, etc., of the World Published by Order of the Lords Commissioners of the Admiralty Pp 508 (London. J D Potter, 1927.) 3s net.

given have practically been functions of the semidiurnal constituents only. More strictly, they are functions only of the constants of particular constituents, maximuch as the effects of changing phase and distance of the moon are not included, though corrections can be made for these conditions. The tidal differences are more general than the constants, as the variations due to phase and distance are included in the predictions for the standard port In any case where the durnal tide is not wholly negligible, large errors are possible, and the error increases with the relative magnitude of diurnal and semidiurnal tides. In general, the non-harmonic constants and differences are of little value outside the Atlantic Ocean.

For heights of tide at times other than high water, the tables and diagrams assume that the tidal oscillation is simply harmonic. This is never the case where there is diurnal inequality and is very rarely the case for ports situated in relatively shallow water

The harmonic method, however, is uniformly applicable, and its results in general are of very much greater value than those of the non-harmonic methods. The computations required are not excessive, and are facilitated by explicit instructions and tables Carefully worked examples are given, and it is difficult to see how misunderstanding can occur The tables to assist predicting are well set out, and the whole work is straightforward and within the powers of any intelligent man. No knowledge of tidal theory is required. The harmonic constants have been given in such a form that the predictions are automatically rendered in the standard time kept at the place, a feature which is unique to the present publication Since the values of mean sea-level with respect to chart datum are given, the mariner can readily obtain the actual depth of water available; other recent publications of harmonic constants have omitted this important quantity.

Approximate methods of harmonic tidal prediction have been published by Van de Stok for use by seamen, and a recent publication by the International Hydrographic Bureau is based on his work. In Great Britain the movement for reform has been initiated by Commander H. D. Warburg, and it has been backed by scientific opinion. The results of his labours are extremely creditable In the opinion of the writer the list of constants, the mode of presentation, and the instructions exceed anything yet published in this line. This serious attempt to reform the methods of prediction, and the progressive policy of the Hydrographic Department of the Admiralty, are very commendable. It is to be hoped that the methods advocated receive a favourable reception by A. T. Doodson. seamen.

### Studies of Ovarian Dynamics.

PROF. LIPSCHUTZ, in an illuminating review of current work on this subject in Biological Reviews, vol. 2, No. 3, pp. 263-280, gives concrete expression to some of the main results which have emerged from the study of ovarian dynamics In the first place, the author shows that the number of primary follicles which enters into follicular development, the degree of follicular ripening which is attained, and the further fate of the follicle, depend not upon the total number of primary follicles present, but upon general internal factors outside the ovary. This he terms the law of follicular constancy, and there is a constancy for each

Secondly, Prof. Lipschutz shows that the time at

ent upon the age of the internal environment and independent of the age of the ovary. Young ovary engrafted into an adult animal will begin its endocrine activity sooner than corresponds to the age of the ovary, and conversely, adult ovary engrafted into a young animal will cease endocrine activity. The ovary is only the means by which sexual puberty is realised when certain environmental factors allow follicular development and endocrine activity (the law of puberty). The influence of body growth on the ovary is next discussed, and it is shown that certain growth substances, not sex specific, which are necessary for both body growth and follicular

which endocrine activity of the ovary sets in is depend-

development, are not available for the latter so long as there is an intensive growth of organs before puberty.

Finally, the sex specific reaction to the ovarian graft is considered, with special reference to the guinea-pig Here castrated males and castrated females behave differently when engrafted each with an ovary of the same female, the male showing rapid and uninterrupted progressive development to a state of hyper-feminisation, while in the female development is slower and interrupted, with a certain amount of regression, and it never attains the same degree of hyper-feminisation nor is there ever milk secretion. This difference is due, not to somatic differences in the sexes, but to the different behaviour of the ovarian graft. due to some unknown internal factors. The author concludes that general internal factors outside the ovary are of fundamental importance equally with the ovarian hormones, in maintaining a normal sexual cycle.

## University and Educational Intelligence.

BIRMINGHAM.—The transfer of the Zoological Department from Mason College to the new buildings at Edgbaston is now completed. The new quarters, which are spacious and well lighted, include a teaching museum and excellently equipped laboratories both for research and routine teaching of all grades. A good departmental library is provided to meet the needs of research workers. Special attention is to be given to comparative invertebrate physiology, experimental embryology, and entomology (including field work).

Mr. Geoffrey Evans has been appointed principal of the Imperial College of Tropical Agriculture at Trinidad. Mr. Evans was in the Indian Agricultural Service from 1906 until 1926. He was for a time attached to the Queensland Government in Australia as director of cotton culture, and during this period he also worked in Fiji, Papua, and New Guinea.

Some experiments in Indian education are described in a pamphlet (Occasional Report, No. 14) recently issued by the Indian Government Bureau of Education. The Dalton plan has been tried with notable success in high schools at Shillong in Assam and at Dacca in Bengal and adapted with good results to the needs of one-teacher primary schools in Assam. Its success at Shillong is the more remarkable by reason of the multiplicity of vernacular languages used in the school and the lack of anything like adequate accommodation. After four years' trial the teachers are enthusiastically in favour of the new method and endeavour to turn even the periods devoted to class teaching into something more of the nature of conferences of teachers and pupils. Experiments at the American Presbyterian Mission training school at Moza in the Punjab have been directed toward evolving a type of education which will succeed in village schools through relating closely to the pupils' village environment all the work, including the practical farm and domestic training, but in such a way as to tend toward the bettering of present village conditions. The principle of 'learning by doing' and the 'project' method are constantly applied, and great attention is paid to cultivating a capacity for self-help. An account of the introduction of a scheme of medical inspection of school children at Simla concludes with the remark that although a feeling of dismay exists generally in India on account of the present neglected position of this work, yet the Simla Municipality congratulates itself that school medical inspection for its boys is equal to that of any town in the West.

## Calendar of Discovery and Invention.

August 21, 1843.—It was during the Cork meeting of the British Association in 1843 that Joule on Aug. 21 read to "an unwilling audience of six" his paper "On the Calonfic Effects of Magneto Electricity and the Mechanical Equivalent of Heat" From the experiments described he obtained the value of 838 ft-lb. for the mechanical equivalent In a post-script to this paper Joule said that he was satisfied "that the great agents of nature are by the Creator's flat indestructible, and that whatever mechanical force is expended, an exact equivalent of heat is always obtained."

August 22, 1765.—In 1713 an Act of Parliament was passed offering sums of £10,000, £15,000, £20,000 to any one who could discover a method of determining the longitude at sea within 60, 40, or 30 geographical miles respectively. The reward of £20,000 was eventually won by John Harrison, whose fourth timepiece, in the form of a watch about 5 in in diameter, during a voyage in the winter 1761–1762, enabled the position to be determined within 18 miles, and during a voyage in 1764 to be determined within 10 miles. Harrison, however, was treated with illiberality by the authorities, who improperly withheld the reward and imposed new conditions. One of the new conditions was that he should give a full explanation of the principles of his timepiece, which he accordingly did on Aug. 22, 1765, in the presence of Maskelyne and six experts appointed by the Board of Longitude. In spite of this, it was not until 1773, when he was eighty years of age, that the final balance of £8570 was paid to

August 22, 1850—In the Statuary Hall of the Capitol, Washington, D.C., stands the statue of Dr. James Gorrie (1803–1855), a pioneer of artificial refrigeration, who was the first to obtain cold by causing compressed and cooled air to expand in working a piston in a cylinder. Gorrie's patent was dated Aug. 22, 1850. He died at Apalachicola, Florida, and his statue was placed in the Capitol by that State

August 24, 1871.—Helmholtz visited Scotland in 1871, and in a letter to his wife from St Andrews, dated Aug. 24, 1871, he referred to a dinner with Crum Brown the chemist and Sylvester the mathematician. Helmholtz in his letters also gave the amusing sketch of Tait: "Mr. Tait knows of nothing else here but golfing. I had to go out with him. My first stroke came off; after that I hit either the ground or the air. Tait is a peculiar form of savage; lives here, as he says, only for his muscles; and it was not till to-day, Sunday, when he dare not play and did not go to church either, that he could be brought to talk on rational subjects."

August 26, 1856.—While a student and assistant under Hofmann at the Royal College of Chemistry, Oxford Street, Perkin, who was then but eighteen years of age, while experimenting during the Easter vacation of 1856 with the object of producing quinine artificially, was led to oxidise aniline, obtaining as the product the colouring matter known as aniline purple or mauve. The new dye was favourably reported on by Pullars of Perth, and it was patented by Perkin on Aug. 26, 1856. The following year Perkin set up a factory at Greenford Green, with the aid of his father and brother, and from this dates the birth of the great coal-tar colour industry.

August 27, 1783.—The use of hydrogen in balloons was due to the French physicist, Charles, whose trial balloon, 3.9 metres in diameter, was released Aug. 27, 1783.

## Societies and Academies.

## PARIS.

Academy of Sciences, July 11.—The president announced the death of M. Mittag-Leffler, correspondant in the Section of Geometry—E. Cartan: The Rieman forms of geometries with semi-simple fundamental group.—G. Pfeiffer: Systems of partial differential equations of the first order with several unknown functions possessing the integral of Hamburger—Soula: The comparison of the two functions  $\Sigma a_n z^n$  and  $\Sigma z^n | a_n$ .—Ernest Esclangon: Observations of the partial eclipse of the sun of June 29, 1927, made at the Strasbourg Observatory. The results of measurements of the times of first and second contacts are given. The weather conditions were very favourable.—Th. Moreux Observations of the eclipse of the sun of June 29, 1927, at Bourges— Raoul Ferrier: The limit of application of the theory of the vector potential.—P. Lasareff The law of viscosity of H. Le Chatelier. This formula expressing Viscosity of H. Le Chatelier. This formula expressing the viscosity  $\eta$  of glass as a function of the temperature t, namely,  $\log (\log \eta/\eta_o) = N - Mt$ , where  $\eta_o$ , M, and N are constants, has been applied to the experimental data of Stott for glass, of Thorpe and Rodger for amyl alcohol, and of Deriaguine and Khananov for solutions of sugar in glycerol. The formula applies in all these cases.—Félix Michaud: Binary mixtures of volatile liquids The case where the two components form a compound.—Emmanuel Dubois: The Volta effect. A metal becomes electronegative with respect to its mittal state if it is heated (in a vacuum) to a sufficiently high temperature. The saline impurities which are normally found on the surface of a metal, and probably also in the body of the metal, may take an important part in these variations.—Nicolas Perrakis: The magnetic study of vanadium tetroxide and trioxide; the measurement of the atomic moment of trivalent and tetravalent vanadium. Whilst vanadium in the state of tetroxide possesses within two well determined intervals of temperature two different moments, the one of 8 and the other of 14 magnetons, in the state of trioxide it possesses a moment of 9.5 magnetons. Edgar Pierre Tawil: Some observations in resonance made on piezo-electric quartz.—R. Descamps: The natural rotatory power, in the ultraviolet, of aqueous solutions of the neutral tartrates of sodium, potassium, and ammonium.—L. Andrieux: A new method of preparing boron. On electrolysing at 1100° C. a mixture of boric anhydride (2 mol.), magnesia (1 mol.), and magnesium fluoride (1 mol.) in a carbon crucible with an iron cathode, there is obtained a deposit on the cathode which consists mainly of boron. After powdering, treating with hydrochloric acid and drying in a vacuum, this deposit contains 92 per cent. of boron—Josef Hrdlička. The influence of the preliminary lighting and the disagreement with the law of reciprocity in photography.-Mlle St. Maracineanu: the special effect of polonium, sunlight, and electricity at high voltage on lead. The results of the experiments described suggest that the formation of a new radioactive substance occurs in the lead sheet.—Deslandres: Remarks on the preceding communication. These results are of great interest but very complex, and their exact interpretation requires much additional research.—Albert Portevin and Etienne Pretet: Study of the velocity of solution of the ultra-light magnesium alloys. A discussion of the methods available for measuring quantitatively the rate of solution.—F. Bourion and E. Rouyer: Determination of some complex compounds by the boiling-point method.—Pariselle: The polarimetric and electrometric study of the alkaline aluminotartrates. A double phenomenon of mutarotation.—Charles  $Pr\'{e}vost$  A new class of tautomeric compounds; the onic theory of tautomerism.—Mile Jeanne Lévy and P. Weill: The reality of the semipinacolic transposition The study of anisylmethylethylglycol From the experiments described it is concluded that the transformation of anisylmethylethylglycol into a ketonic product different from that furnished by the aldehydoketonic transposition of anisylmethylbutanal demonstrates the reality of the semipinacolic transposition. In the semipinacolic transposition the ethyl radical shifts more easily than the methyl radical.—Edouard Roch: The western extremity of radical.—Edouard Roch: The Western extremity of the Djebilets massif (Morocco).—P Russo: The presence of Archæocyathus in the Djebel Ighoud (Western Morocco).—V. Agafonoff: The zones of the soils of France.—J. Dufay: The intensity of the green line of the polar aurora in the spectrum of the nocturnal sky.—Edouard Salles: The fixation of the radioactivity of the air by the terrestrial electric field. -Henri Coupin: The carbon nutrition of Penicillium glaucum by means of various carbon compounds of the aromatic series. Compounds of the aromatic series are much less favourable than compounds of the fatty series for securing the carbon nutrition of Penicillium glaucum, and this is probably true also for other moulds —M. Bridel and Ch. Aagaard: Is melezitose a combination of saccharose with glucose? The experiments described do not confirm the view of Kuhn and van Grundherr that melezitose is a combination of saccharose and glucose.-A. Demolon and G. Barbier: Elective ionic absorption in colloidal clay.-Mme Lucie Rabdoin and René Fabre: Comparative researches on the glutathione content of some tissues and blood in the normal pigeon, the under-fed pigeon, and the pigeon deprived of B vitamin.—C. Arnaudi, W. Kopaczewski, and M. Rosnowski: The physico-chemical antagonisms of micro-organisms.

## CAPE TOWN.

Royal Society of South Africa, May 18.—Lancelot T. Hogben: A method for the study of dissociation of hæmocyanin. An elaboration of the method proposed by Pantin and Hogben (1925) for studying the dissociation of the oxyhæmocyanins is described. It is possible to plot a five-point dissociation curve within a quarter of an hour with sera of arthropods and molluses which can be kept indefinitely in the laboratory with prescribed precautions.—Sir Thomas Muir: The theory of Hessians from 1883 to 1914.—S. H. Haughton: Note on some features of part of the Orange River valley. Dealing with the geographical features of the Orange River and its northern tributaries, the gorge-like nature of the valley and its independence of the geological structure of the country were discussed; and the unity of the Great Fish River and the lower part of the Orange was suggested.—A. J. H. Goodwin: Archæology of the Vaal River gravels. Ever since the discovery of diamonds in the Vaal River gravels, stone implements of a large almond-shaped type have been discovered and submitted to various museums, especially the McGregor Museum, Kimberley. The gravels are situated at intervals along the Vaal River, sometimes at a considerable distance from the river, and at various levels above the river bed. They are disjointed, and form various small groups, each of which is a time sequence in itself. The lowest gravels are the latest, and are often in actual process of formation. The highest are probably the earliest. These terraces cannot be dated with any degree of accuracy, but from the fossils discovered we must

regard the earliest (highest) as being of Lower Pleistocene age. The implements appear only in the lower terraces, and must therefore be regarded as of later date than the Lower Pleistocene, owing to the complete lack of such implements in the oldest terraces. These implements are of a type similar to those described by Péringuey as of 'Stellenbosch' type, but the technique approximates more closely to the culture described by Mr. C. van Riet Lowe, from Fauresmith, O.F.S, due possibly to the similarity of material. The Vaal River sites also show that the smaller implements, popularly called 'Bushman,' are of far later date than the large almond-shaped types.—P. R. v. d. R. Copeman Studies in the growth of grapes (Part n.): Relationship between sugar and acid in the juice. There is a very high degree of negative correlation between these two factors. The regression lines are not, however, linear, but the acid may be expressed in terms of the sugar by means of the equation  $(y-a)^n = A/x - B$ , where x and y are the sugar and acid respectively and a is the minimum acidity. This equation is only applicable during the period of decrease of acidity.

#### GENEVA.

Society of Physics and Natural History, June 16 .-L. Duparc: Some chromite deposits of Thessaly. The author has examined several deposits now being worked in the Katarini region as well as the outcrops in the vicinity. These are basic segregations in the serpentinised peridotites.—Amé Pictet and Hans Vogel: The synthesis of maltose. This substance has been obtained by heating in a vacuum at 150° C. a mixture of  $\alpha$ -glucose and  $\beta$ -glucose. At this temperature the a-glucose is transformed into glucosane; the  $\beta$ -glucose is not dehydrated and it forms an addition product which is maltose.-G. Menkès Researches on the action of vitamins on the fungi. Experiments made on various cultures of Aspergillus show that an alcoholic extract of tomato containing vitamin principles, principally factor B, accelerates the growth of the mould and facilitates the assimilation of sugar, in agreement with results of observations made on animals.—M. Hausmann: synthesis of ethyl galactoside in media with different pH The author proves by experiments on the synthesis of ethyl-galactoside by means of emulsm, that the variations of the pH of the medium influence the ferment in its synthetic functions and that this influence is identical with that exercised on hydrolysis. -M. Hausmann: The molecular proportions to be observed in the cresol blue reaction (tyrosinase). In testing for the best molecular proportions for the formation of the colouring matter known as cresol blue produced by the action of the tyrosmase ferment on a mixture of glycocine and paracresol, the author shows that an equimolecular proportion of these two substances is clearly not the best, and that the optimum is attained by a mixture of four molecules of p-cresol with one molecule of glycocine.—Ch. G. Boissonnas and E. Briner: The oxidation of nitrogen by ozone. By experiments carried out at the ordinary pressures and at temperatures between 20° C. and 200° C., as well as in experiments under a pressure of 120 atmospheres, it is shown that ozone is incapable of oxidising nitrogen.

#### SYDNEY.

Linnean Society of New South Wales, May 25.— C. P. Alexander: The interpretation of the radial field of the wing in the Nematocerous Diptera, with special reference to the Tipulidæ. A new interpretation of the radial field of the wing in the Diptera. —Dudley Moulton: New gall-forming Thysanoptera

of Australia. Four new species belonging to four different genera, one of which is new, are described. Miss H Claire Weekes: Note on reproductive phenomena in some lizards. An omphaloplacenta and an allantoplacenta occur in the scincid lizards Lygosoma quoyi, Egernia whitei, and E striolata. The allantoplacentation in L. quoyi more closely resembles that found among the Mammalia than any hitherto recorded in a reptile, there being a partial degeneration of maternal and fœtal epithelial tissue allowing for a close proximity of maternal and feetal bloodstreams. Corpora lutea occur in the ovaries of all the above species and in *Tiliqua scincoides*. The extra-embryonic mesoderm in all four species dips into the yolk-sac endoderm and grows round the yolk-sac embedded in its substance, and not over its surface as is usually the case.-J. McLuckie and A. H K. Petrie. An ecological study of the flora of Mount Wilson (Part iv ) Habitat factors and plant response. The two factors of outstanding significance in controlling the distribution of the vegetation at Mount Wilson are aspect and moisture-content of the soil The Malayan Rain-Forest flora (Ceratopetalum-Doryphora Association) is a mesophytic community which has survived in the most favourable habitats provided by the basalt residuals and the deep sandstone gorges which dissect the area.

Royal Society of New South Wales, June 1.—A. R. Penfold and F. R. Morrison · A critical examination of Eucalyptus dives and the occurrence of a number of varieties thereof as determined by chemical analysis of the essential oils (Part 1.). Three varieties, indistinguishable from the type on morphological grounds, have been determined by chemical analysis.—J. C. Earl: The preparation of tetramethylethylene. A new method utilising several known reactions has been devised. The scheme of reactions is amylene hydrate -> trimethylethylene -> trimethylethylene  $chlorohydrin \longrightarrow dimethylisopropylcarbinol \longrightarrow tetra$ methylethylene. The yield is good, and the process can be interrupted at any stage without risk of deterioration of the intermediate products.—Sir George H. Knibbs: Protogenesis and ex-nuptial natality in Australia The maximum frequency of ex-nuptial births occurred during the period 1899 to 1907; it may be subject to long-period oscillations. The frequency both of nuptial and ex-nuptial cases at the beginnings and endings of the reproductive life, show that both growth and decay are approximately but not exactly exponential. Both commence at about 12 years of age, but the relative frequency, compared with the numbers at risk, is much less for ex-nuptial cases than for nuptial. At age 16.4 the actual numbers are, however, equal. The actual phenomena of nuptial first-births, according to the ages of the mothers, can be represented by three co-ordinates, x denoting age, y denoting the duration of marriage, and z denoting the relative frequency of first-births corresponding to particular ages and durations of marriage. The protogenesic surface discloses the continuity of the phenomena for intervals of less than nine months from marriage with those for all intervals up to 27 years. Fertility varies with age and with time. For births within 9 months of marriage, it was greatest for say 1910.0 and also for 1919.0 for age 21, the numbers for 10,000 women of that age being respectively 1281 and 1248. For all first births it was for age 22 for 1910 0, 23 for 1915 5 and for 1922.5, the respective numbers per 100,000 mothers being 9401, 9363, and 8706. The averages for the year 1917.2 were 1256 and age 21 for births up to 9 months after marriage, and 910 for age 23 for all first births. These are maximum ages and

fertilities The maximum intensity of the gonad urge would appear to be for age 21.3 years both nuptially and ex-nuptially.

#### WASHINGTON, D.C.

National Academy of Sciences (Proc., Vol. 13, No. 5, May).—Joel H. Hildebrand: A quantitative treatment of deviations from Raoult's law. Plotting  $\log N_2$  against 1/T, where  $N_2$  is the mole fraction of the solute, shows that many solvents give with each solute a characteristic group of curves. Dealing with binary mixtures, an extension of Raoult's law is obtained from which several physico-chemical quantities can be calculated —Oliver R. Wulf and Richard C. Tolman The thermal decomposition of ozone. Homogeneous decomposition can be made to proceed so as to be closely of the second order with respect to ozone, the specific rate for different samples may vary considerably but is generally, for ozonised oxygen, inversely proportional to the total pressure. This is considered to be due to the inhibiting effect of oxygen on the decomposition .- C. M. Cleveland · Concerning points of a continuous curve that are not accessible from each other .- O. E. Glenn: Recent progress of investigations by symbolical methods of the invariants of bi-ternary quantics -C. F. Roos: A dynamical theory of economic equilibrium. For equilibrium in a co-operative society, a functional operator must be maximised; for a competitive society, partial maxima of several functional operators must be obtained —Lester R. Ford (1) On the foundations of the theory of discontinuous groups of linear transformations. The concept of the isometric circle of a linear transformation is applied to such groups. (2) On the formation of groups of linear transformations by combination.—Erich F. Schmidt: A stratigraphic study of the Gila-Salt region, Arizona. The ancient pottery falls into three groups, Gila polychrome, black-on-white, and red-on-yellow. The distribution of the sherds with depth in the excavations indicates that the Lower Salt (red-on-yellow) is older than polychrome and was probably made by the builders of Pueblo Grande. The red-on-yellow was synchronous with the black-on-white.—Charles F. Meyer and Aaron A. Levin: The infra-red absorption spectra of acetylene  $(C_2H_2)$ , ethylene  $(C_2H_4)$  and ethane  $(C_2H_6)$ . The range  $3\mu$  and  $15\mu$  was examined and the absorption bands are found to show definite structure. Acetylene has a band (13  $7\mu$ ) showing an intense central Q-branch, an R-branch showing wellmarked alternation of intensity of the lines, and a P-branch with less marked alternations.—G. W. Fox, O. S. Duffendack, and E. F. Barker: The spectrum of CO<sub>2</sub>. A continuous flow method was used A stream of pure carbon dioxide was passed slowly into the discharge tube and subjected to electron bombardment in a force-free space before reaching the filament. None of the bands generally attributed to carbon monoxide was observed. The carbon dioxide spectrum extends from 5000 Å.U. to 2800 Å.U. and consists of bands of various types.—Gilbert N. Lewis: The entropy of radiation. Assuming that radiation can be divided into slices of constant entropy independent of the presence of other slices, and that the chance of a particle being in a selected volume is a linear function of the number of particles already in that volume, Planck's entropy equation is obtained as a first approximation and a further approximation is indicated.—Carl Barus: Linear elements of the electromagnetic pinhole graphs.—Edwin H. Hall: Thermionic emission and the "universal constant" A. An equation for thermionic emission is derived by utilising the dual theory of conduction. In form it is similar to Richardson's equation, but the factor

corresponding to A is variable. - H Bateman . Lagrangian functions and Schrödinger's rule —F. D Murnaghan and K F Herzfeld Two remarks on the wave-theory of mechanics The degree of arbitratiness m the wave-equation and the energy-frequency relation are discussed.—K. T. Compton and C. C. Van Voorhis: Heats of condensation of positive ions and the mechanism of the mercury arc. If neutralisation of the ion occurs at or just outside the surface of the electrode, half the energy is lost by radiation and a portion by reflection. Then the heating of the cathode is given by  $\phi_- = r V_i + L - \varphi_e$ , where  $V_i$  is the heat of recombination of an ion and an electron, L the latent heat of condensation of the neutral gas,  $\phi_s$  the heat of evaporation of an electron, and r is a factor less than 0 5 by an amount depending on the reflecting power of the electrode. In the mercury arc, the electrons are drawn out by the intense space charge (Langmuir) and mercury is lost from the cathode as drops consisting of numbers of atoms -R. J. Lang · Series spectra of silver-like atoms. The first members of each of the four ordinary series for In III., Sn IV., and Sb v. have been identified —J B. Green and R. A Loring: Term-structure and Zeeman effect of the arc spectrum of tin (preliminary report).

## The Expert in the Civil Service.

ERTAIN important considerations in connexion with the position of the expert in the Civil Service are raised by the retirement of Sir Frank Baines from the position of Director of Works to His Majesty's Office of Works. Some months ago Sir Frank Baines was approached by a former First Commissioner of Works, Sir Alfred Mond, to undertake the construction of a headquarters on a site in Westminster for the Imperial Chemical Industries, Ltd Sir Frank Baines applied formally for permission to add to his responsibilities in this way, and, following precedent, this permission was granted Later, certain members of parliament discovered that the new building involved an outlay approaching one million pounds, and asked if an architect carrying out such a contract could devote his proper attention to his duties as a civil servant The official reply to the first question, put on May 26, was to the effect that the Government had no right to interfere with the spare time activities of a civil servant, and that this particular contract would not militate against the efficient performance of Sir Frank Baines' official duties. Within a month the Government came to the conclusion that its Director of Works should either cancel his contract with Imperial Chemical Industries or retire from the Civil Service, although, as it was stated by the Government spokesman, Capt. Hacking, there was no suggestion that the work in connexion with the undertaking had so far interfered with the director's official duties.

Now it has been stated on several occasions within recent years that the professional, technical, and scientific staffs in the permanent employment of the State should have their pay and other conditions of service related to those of their professional brethren in outside practice. It was on those grounds that the Anderson Committee reported to Parliament in 1923 that no modifications in the pay or other conditions of service of professional civil servants need be made. Obviously, however, if the case of Sir Frank Baines is to be taken as a criterion, the conditions of service are not the same inside the Civil Service as in outside practice. An outside architect would feel at liberty to increase his practice to any extent, and would be the last person to suggest that he was not capable of undertaking any and every commission offered to him. London is full of monuments eloquent of the efficiency and energy of Sir Christopher Wren. Had the conditions of our time made it possible for Imperial Chemical Industries to invite the Office of Works to undertake the contract for their new building, it is safe to say that no question would have been raised as to the capacity of the Director of Works to do the work without interfering with his other duties.

Without doubt the knowledge gained from long experience in a technical department of State, places the State servant in a position of advantage as compared with the private practitioner. Presumably, it is this knowledge which Sir Alfred Mond wished to put at the disposal of his company, just as the directors of the Bank of England have sought the services of Sir Otto Niemeyer, and the fortunes of Nobel Industries, Ltd. and later of a railway board have in turn been brought under the direction of Sir Josiah Stamp. But a nearer parallel to the case of Sir Frank Baines is to be found in the universities. At one time university professors were rarely consulted by industry or by the Government. Nowadays, largely as the result of the unique services rendered by university staffs to the country during the War, university men of science are being actively encouraged to undertake consulting and research work, for private firms and for the Government. Again, in the Report of the Committee of the Privy Council for Scientific and Industrial Research for the year 1925-1926, special reference is made to the growing volume of work undertaken by Government scientific departments, particularly the National Physical Laboratory, on behalf of industry, and no suggestion is made that the quality of the work of the research staffs suffers in consequence of its increased responsibilities in this direction. Moreover, in the Report of the same committee for the year 1924-1925, reference is made to the increasing volume of consultative work for industrialists undertaken by the State-aided industrial research associations, work which would ordinarily have been done by private consultants.

Not only does the State encourage members of university staffs to undertake additional responsibilities, not only does it compete with the private consultant in industry, but it also appoints State servants to the boards of the State-subsidised industrial research associations in order that knowledge acquired in State departments should be made known and become available to our various industries. Within the past two or three years it has lent scientific workers to some of the great shipping companies to investigate the problems in connexion with the safe transport and

storage of foodstuffs, and wholly maintains State research institutions for the primary object of assisting vital industries.

On account of an organised agitation, however, against the unique knowledge possessed by one of its principal technical experts being made available to an industrial combine, a new attitude seems to be presented to such relationships. The real objection to Sir Frank Baines undertaking a building contract for the Imperial Chemical Industries is based upon the fact that he personally was to profit by the transaction—particularly as the profit was assumed to be large. Neither of the obvious ways of dealing with the situation appear to have been considered The Government could have suggested that the contract should be undertaken officially by its servant on behalf of the Office of Works, and incidentally made it known at the same time that the Government was prepared to tender in the open market for any similar undertaking. Alternatively, it might have given its technical expert sufficient leave of absence to enable him to complete the contract into which he had entered with the full authority of his Furthermore, it might carefully have department considered the desirability of putting the direction of one of its most important technical departments under a man who enjoys the confidence of one at least of the foremost industrial leaders of the time, instead of abolishing his post. Under the present system, however, technical experts in Government service are usually subject to admmistrative officers lacking technical qualifications and experience.

Parliament has been promised that the conditions of service of members of the professional staffs of the Office of Works shall be reviewed. Presumably a Treasury Committee will undertake this task, and an attempt be made to tighten up the existing regulations regarding the nature of any work with which professional civil servants may occupy their private time H M. Treasury is, of course, in a position to impose what regulations it likes, but it may be suggested that in doing so great care should be taken to avoid any semblance of unfair discrimination against a particular section of the Civil Service. What is really needed is the appointment of a Royal Commission to examine and report on the present position of the professional worker in the State service, and to determine what modifications of the Civil Service system, if any, are desirable to meet the changed conditions resulting from the growing impact of the State on industry as a whole.

## The Ascent of Man.

THROUGH the centuries a philosopher here and a naturalist there toved with the notion that man was somehow linked by nature with the animal kingdom, but the notion lacked concreteness and was not taken seriously Then came Charles Darwin, first with a theory of the evolution of organic beings which involved the ancestry of man, and sixteen years later with a cumulative study ( The Descent of Man," 1871) which clinched his argument, and could no longer be Man took his place at the summit of the tree of organic evolution, and as the topmost branch draws the lightning so the ancestry of man became the target upon which were concentrated the thunder-bolts of a fierce opposition Until then, the battle of evolution had been waged upon a long front, but no sooner had the 'origin of man' entered the field than the zone of fiercest combat became narrowed, and to believers in the old creed the descent of man became the salient by the fate of which the whole long front of evolution was to stand or break.

Half a century has come and gone since then: new facts have accumulated and been assimilated. and while evolution has won its battle and become part of the stock-in-trade of the world's thought. a sporadic fight still wages about the isolated salient of man. That it is no mock combat is shown by the numbers of combatants who rushed to the support of the Fundamentalist position in the United States of America a short time ago, and any one familiar with the attitude of mind of the average Briton must be aware of the latent hostility which still survives towards the idea that, in popular phrase, 'man sprang from a monkey,' and of the satisfaction with which the emergence of each new scientific squabble regarding interpretation is hailed as the rift indicating the approaching dissolution of the whole.

At the present moment the critical attitude towards the reality of human evolution is at the top of one of its periodic swings. The reason for the fresh recrudescence of opposition can be easily traced. Charles Darwin's statement of the doctrine of evolution fell upon a scientific world which had been groping for light, and after the first fierce clash with the 'die-hards' of the old order, the grandeur of his concept, its plain logic and simplicity, lulled the scientific world into a stupor of complacency. Biologists accepted the Darwinian revelation; they rushed to weave their fresh examples into its mesh, and with facile interpretation naturalists, profes-

sional and amateur, explained with satisfaction the evolutionary significance of each and every structure as it came to their notice. It must be remembered that Darwin laid the weight of his argument upon the structures of organisms, and passed lightly over the vital problems of functional adaptation and of the correlated development of structures, the prime importance of which is now becoming manifest.

However, the first inhibiting glamour of a great thesis wore off The study, especially of variation, heredity, and the correlation of structures and activities, led to a critical examination of Darwin's conclusions: and while the doctrine of evolution has never been gainsaid, one and another has arisen to show that the course of evolution has not been determined exclusively or mainly by the natural selection or the struggle for existence upon which Darwin laid stress. Two recent works of different character may be cited as illustrating the critical attitude of scientific workers towards natural selection, both, strangely enough, founded upon the study of fishes—Berg's "Nomogenesis" (1926) and Kyle's Biology of Fishes" (1926).

This scientific revolt against the easy acceptance of 'Darwinism' had already gained much ground when it compelled the attention of the people by the publicity given to Bateson's address to the Toronto meeting in 1921 of the American Association for the Advancement of Science, and by the directness and vigour of his attack. The disturbance of accepted theories and ideals by the long years of war had prepared the ground. The popular mind leapt to the conclusion that the apparently established belief in evolution had been shaken, and the critics of the simian origin of man rushed to the fray. Typical of their statements was the contribution of a prominent Boston pastor to an American newspaper, in which he gave the names of "some scientists who at least call in question the loudly asserted proof of evolution," and the names included those of J. P. Lotsv. W. E. Ritter, Paul Kammerer, and E. W. MacBride! Of course, the pastor and his sympathisers were mistaken These men of science had made their declarations with clearness and in full knowledge of the implication of their words. It was only a thoughtless misinterpretation or the blindness of bias which construed their attacks and those of Bateson, Morgan, and the rest, into an onslaught upon the great truth of evolution or descent by modification, instead of, as they really were, critiques of the method - natural selection - by which Darwin supposed evolution to have worked its way. Mistaken though the reading of scientific progress was, it is this mistake which has given new life to the present-day attacks upon evolution, and has induced doubts in many minds, unfamiliar with the trend of scientific achievement, regarding Darwin's view of man's development, and especially of the merging of human ancestry in a common stock with the forerunners of the simina apes.

A restatement of the position in the light of modern knowledge—a simple, convincing statement, unencumbered by detail and side-issues, vouched for on the word of authority—would serve a very useful purpose at the present time glad, therefore, that Sir Arthur Keith has chosen the subject of "Darwin's Theory of Man's Descent as it stands to-day "as the theme of his presidential address to be delivered at the Leeds meeting of the British Association next week. No man is better qualified than Sir Arthur to meet the need of the time-by training, experience, prestige, and by the touch of fervour and imagination which he has carried from northern Scotland. Though the address will be delivered to a body of men and women familiar in the main with the scientific mood and the general conclusions of science, and, enlightening as it is sure to be, can, therefore, scarcely do more than confirm conviction, yet it will reach a wider audience through wireless and the press, and may be expected once again to focus attention throughout the English-speaking world upon the essential verities of man's ascent, and place a fresh strain upon the incredulity of unbelievers.

## Language and Culture.

Die Sprachfamilien und Sprachenkreise der Erde.
Von Pater W. Schmidt. (Kulturgeschichtliche
Bibliothek, herausgegeben von W Foy. Reihe
1: Ethnologische Bibliothek, Band 5.) Pp.
xvi+596. Atlas von 14 Karten. (Heidelberg:
Carl Winter's Universitatsbuchhandlung, 1926.)
42 gold marks.

THIS work falls into two parts, of which the first contains an enumeration of the languages of the world under more or less accepted headings, but an exception to the general rule is made for what are commonly called the Sudanic languages, for which two wholly inconsistent schemes are printed, one by Delafosse, the other by Drexel. The second part consists of a discussion of the distribution of certain features of phonetics, grammar, and syntax, followed by a reclassification of the languages on the basis of the data in question; the primitive position of the dependent

genitive is then dealt with, together with the causes which brought about a change, and finally the relation of linguistic to cultural areas is discussed.

No final verdict can be passed upon the book until specialists for each area have sat in judgment and accepted or rejected, so far as they concern their own special provinces, the theories put forward, but whatever criticism in detail may be launched at the author's head, the work will remain as a great achievement, truly remarkable as the product of one man. Perhaps no one but Pater Schmidt would have had the courage to attempt it, or, if he attempted it, to bring it to a successful conclusion. For the author is far from retraversing well-trodden paths, he has opened a vista of new lines of research which cannot fail to attract many workers.

Where so much turns upon contact between different groups, it is of course essential to have a thoroughly accurate topographical basis for the theories; the linguistic data must be as complete and accurate as possible; and the conclusions must be wholly without ambiguity. To what extent these three essentials have been attained, so far as one area is concerned, will be made clear in the sequel. It is only fair to state that the author in his preface invites criticism in detail and looks forward to a second edition free from the errors which are bound to appear in a pioneer work.

Following Drexel in the main, the author groups Sudanic languages under seven heads: Wule (that is, Ubanghi group), Ngo-Nke (Mande), Manfu (Kwa and Central), Kanuri, Nilotic, Bantoid, and Hausa; in the excellent atlas are shown the areas occupied by these groups and their zones of influence. Unhappily there are serious errors in the territory ascribed to the Mande and Kanuri tongues; Hausa extends three degrees too far north, ghost languages (for example, Gogo and Kandin) appear, and the treatment of the northern provinces of Nigeria is demonstrably almost pure guesswork. Over and above this, Gola is located in the middle of the Kru tongues and Bullom north of Konakry in a Susu area; and a nonexistent range of Bantoid is shown south of the Mande group.

Topographical errors are not confined to the maps; Biafada is in the text located on the Senegal instead of the Rio Jeba, Wolof is put in the Senegal group: Serer, its immediate neighbour, forms with Kisi and Fula a north-east group; but Kisi hes far to the south near Gola, and Fula stretches in a series of groups, mostly small, from a

few score miles from St. Louis in the west as far as Lake Chad. To add to the confusion. Biafada, Serer, and Fula are said to meet the Togoland and Mosi-Grusi groups in the extreme north-east on the upper Niger. But Biafada and Serer are about 1000 miles from Togoland, Fula is not in contact with Mosi on the Niger at all, and the prefixes of Tem have nothing to do with Fula, which is a suffix language. De Martonne's atlas, now in a second edition, appears to have been entirely neglected

When we compare the linguistic data of the text with the maps more errors and serious conflicts emerge; the Wule and eastern Manfu tongues, and all the languages of Nigeria and Kamerun, are shown as making the genitive follow the noun it qualifies, while the subject pronoun follows the verb. But at least a dozen Nigerian languages make the genitive precede, the subject pronoun is almost universally placed before the verb, as indeed the text asserts for Manfu and Wule. The text is also in disagreement with the map as to the location of two languages, Huku and Afo, to which a system of senary numeration is assigned. neither is senary in point of fact, and Huku is near the great lakes, not on the Juba, Afo on the Benue, not the Sanaga. Both text and maps wholly ignore the duodecimal systems of the Bauchi plateau.

It is clear that errors and omissions of this kind go far to compromise the author's conclusions when he proceeds on the basis of linguistic data to define the areas of primitive, primary, secondary, and tertiary speech groups; it may be remarked in passing that, singularly enough, many of the families and groups of the first part of the work have to be split up to make them conform to the new classification.

In Africa the southern primary type includes the Mande and parts of the Manfu, Wule, and Bantoid groups, the northern type includes Hausa and also Kunama, wrongly assigned to the Hamitic family; the middle type is represented by Kanuri and the Manfu group, which thus The secondary type in Africa is appears twice regarded as a product of the southern and middle primary types, it includes Bantu and some Bantoid tongues. Singularly enough, the section on secondary and tertiary languages enumerates among the former Nama and Sandawe, which have previously figured as primitive forms of speech, while Kanuri and Hausa, elsewhere regarded as primary, are also reckoned as tertiary.

Space will not permit the citation of further points in which Pater Schmidt will probably have

to make changes in another edition. It is, however, quite possible to make errors in working out the detail of a theory without invalidating fundamental principles. Attention may now be turned to some of the general principles which the author accepts as axiomatic. In the first place mention may be made of the wide use of psychological arguments in relation to linguistic facts; no doubt, if we could discover the real springs of action, psychology could be made to explain linguistics; but it is quite another matter for a European linguist to argue that because a matter presents itself to him in a certain light, therefore it must be so. The question at issue is one of fact, not of what seems likely.

A case in point occurs when Pater Schmidt is treating of different kinds of gender in nouns; he holds that a two-gender (masculine and feminine) system like that of the Hamitic languages is later than that of the Indo-European languages which have also neuter, as an explanation is given that in the two-gender system feminine and neuter have, for reasons which he sets forth, joined forces and become a single class. If we had no linguistic data on which to go this kind of argument might be admitted, but in Indo-European languages, the primary distinction is between animate and inanimate, that is, masculine and neuter, for these two alone differ in form in the noun, the masculine noun cannot be distinguished from the feminine noun in this way. The obvious conclusion is that the feminine is of late origin.

A second example of this kind of reasoning is found in the passage which explains how the prefix genitive became a suffix genitive. It is put down to the rise of matrilineal or matriarchal conditions, which resulted from the introduction of agriculture; agriculture led to a demand for more land, and this to migration and disturbance of boundaries; the meeting of heterogeneous speech forms resulted in the break-up of both, and from this issued the more logical suffixed genitive. This theory involves a good many assumptions, some of them demonstrably not in accordance with facts. Pater Schmidt's map shows matriarchy and the suffix genitive in south-east Australia, but this was not a result of the domestication of plants, which was unknown. Even more unfavourable for the author's contention is the picture presented by America, where matriarchy seems to be in a great majority of cases associated with the prefixed genitive. The major defect of the argument is, however, the assumption that domestication of plants meant land hunger; for it reduced immensely the area needed by a given number of people for their support.

When we recall how little we know of the origins of Indo-European languages, which in some areas were reduced to writing many centuries ago, it may seem, not without reason, hazardous to survey all the speech forms of the world and explain their relations and transformations. But new ideas have a value apart from their correspondence with facts, and pioneer work like that of Pater Schmidt is deserving of all praise.

# The Nitrogen Industry.

The Atmospheric Nutrogen Industry with Special Consideration of the Production of Ammonia and Nitric Acid. By Dr Bruno Waeser. Translated by Dr. Ernest Fyleman. Vol. 1. Pp. xxv1+330. Vol. 2. Pp. 331-746. (London J. and A Churchill, 1926.) 42s net.

THE original German edition of this work was published in 1923. It contained practically all the information which could be obtained from the literature up to March 1921. It has been the author's intention to make it a standard work by including a large number of economic data and a detailed survey of the literature. Vol. 1 contains a short general introduction and then a historical account of the nitrogen industry in each country of the world. Vol. 2 gives a technical description of the processes used in the nitrogen industry. The author has also included allied processes which may be important from their economic effect on the main industry. There are very complete indexes, bibliography, and list of patents.

In order to bring the first German edition up-to-date for translation, there is at the end of each chapter a supplement containing new matter covering the years 1921–1924, and a foreword of seventeen pages has been written by Dr. J. F. Crowley. The supplements consist, for the most part, of bald references to the literature and make an unsatisfactory ending to each chapter, but Dr. Crowley's foreword successfully summarises the position of the industry.

The importance of nitrogen in commerce arose during the Middle Ages from the use of saltpetre in making gunpowder. The nitrogen problem was as acute in France during the Napoleonic wars as in Germany during the late War. Prevented by the blockade from importing adequate supplies of nitre, France had resource to nitrate plantations (saltpetrières), which were administered by a State department. In these plantations heaps of animal

and vegetable refuse were allowed to rot for months until covered with a layer of saltpetre But after the Napoleonic wars, when swords were turned to ploughshares, morganic nitrogen was not turned to agriculture It was not until about 1840 that Liebig showed that inorganic nitrogen compounds were important soil fertilisers From that time the use of inorganic nitrogen in agriculture has grown steadily. At first Chile nitrate was the sole source of supply; then came, in addition, ammonium sulphate obtained from coal, and within the last twenty-five years synthetic nitrogen compoundsnitrate of lime, cyanamide, and ammonia. The development of the synthetic nitrogen industry took place first where electrical power could be obtained cheaply—principally in Norway, because the arc processes absorbed much electrical energy.

Some years before the War Germany had become anxious to produce synthetic nitrogen fertilisers for her soil. A continental nation with no foodproducing colonies, that country was attempting to produce all the food it required. Tariffs were put on imported food, but Germany had to import large quantities of nitrogen, and in 1913 it absorbed 27 per cent. of the total nitrate exported from Chile, as well as nitrate of lime from Norway and sulphate of ammonia from its own coal industries. During this year (1913), 32 per cent of the world's production of inorganic nitrogen was used by German agriculturists. How different were the conditions in Great Britain with free trade, large investments abroad, food-producing colonies, and a large navy!

When the War broke out, Germany, expecting a short war, appears to have attached no importance to the supply of nitrogen for explosives. Later, when the blockade became serious, Germany looked first to her cyanamide factories for nitrogen, and only later did the German Government realise the possibilities of the Haber Bosch process of ammonia synthesis which had just been established in 1913. Two large factories were erected to provide the war requirements. Since the War the German synthetic ammonia factories have been utilised for the production of fertilisers, and works using somewhat similar processes are now active in other countries -England, America, Italy, France, and Belgium. Some of these (England and America) are well established and are already a commercial success. Others are still passing through tribulations and troubles.

The tendency of modern industry is to build large factories, because greater efficiency is obtained with large machines than with small ones, and the

cost of labour for a given output usually decreases as the size of the unit plant increases But more important still is the advantage of better scientific and technical control of processes which can be obtained in a large factory. Dr. Crowley in his introduction seems to attach great importance to a claim of simplicity of one process (Casale), though it is difficult to find the basis of the claim. He states: "On a visit to an important synthetic ammonia plant paid some twelve months ago, the writer found that the whole plant was being operated under the direct supervision of the engineer responsible for the running of the power station, and that no chemists were employed." It does not seem probable that this plant will long survive in competition with plants controlled by the best technically trained men of to-day.

## An Atlas of Rainfall.

Royal Meteorological Society Rainfall Atlas of the British Isles. Prepared under the direction of a Committee of the Society. Pp. xii +44 maps. (London: Royal Meteorological Society, 1926.) 15s. net.

TIWENTY years ago the collection and publication of meteorological statistics in Britain was divided between the Royal Meteorological Society, the Scottish Meteorological Society, the British Ramfall organisation, and the Meteorological Office. To-day this work is all done by the Meteorological Office, and the preparation and issue of a climatological atlas would be a natural obligation of that institution. But, as Dr. Mill explains in his admirable introduction to the volume under notice, the endowment fund of the British Rainfall Organisation was instituted for the advancement of research in rainfall, and no application of that fund could have reflected more honour on the memory of Symons and Salter (and, one may add, of Dr. Mill himself) than its utilisation for the preparation of an atlas of rainfall Incidentally it enabled the atlas to appear at an earlier date than would otherwise have been likely.

The preparation of a rainfall atlas for a country where the variations are so marked as they are in the British Isles, presupposes the collection and analysis of an enormous number of observations; and above and before all others, credit must be given to the 10,000 observers whose work, for the most part entirely voluntary, during the past sixty-six years provided the material.

The frontispiece of the atlas is a good orographic map of the British Isles, a chart essential for the

right understanding of the maps of rainfall which follow; and to meet a very natural desire, three full-page maps are given showing the average annual rainfall, the rainfall of the wettest year, 1872, and the rainfall of the driest year, 1887. Nearly every patch of colour (high ground) on the orographic map has its corresponding patch of deeper blue (heavy rainfall) on the chart of average rainfall.

There are two main series of maps The first comprises small maps (scale I in 8,000,000) of annual rainfall for each individual year for the fifty-six years, 1868–1923, expressed as a percentage of the average for the standard period of thirty-five years, 1881–1915. An examination of these maps shows that though there were three years (1872, 1877, 1903) in the period with rainfall everywhere above the average; there was only one year, 1887, with rainfall everywhere below the average

The maps show, too, how frequently the regions with the greatest percentage excess of rainfall are not the wet mountainous western districts but the plains and lowlands where the normal rainfall is moderate or low. This series of charts presents a historical summary which cannot fail to interest the student of rainfall, the economist, the water engineer and the reminiscent citizen.

The second series includes twelve full-page maps of average monthly rainfall. Though these are of much greater practical importance than the series of annual maps for individual years, they do not make quite the same appeal to the imagination: averages never do. So it is good that the committee included the annual maps, and it would have been even better, had space permitted, to have had a map for each of the 700 individual months of the period. The reader naturally wants to see if 1872 was as thoroughly disastrous for the farmers of Cheshire, Stafford, Derby, and York as the annual map suggests: that depends on the months in which the 70 per cent. excess in those counties was accumulated, but no information can be derived from the atlas on this point Actually, 1879 was far worse for agriculture than 1872, though the rainfall for the whole year in 1879 was generally much less than in 1872.

The monthly maps reveal many unexpected and interesting features: for example, Norfolk has more rain in July than any part of east and southeast England except the high ground of the Downs. September has a larger dry area than any of the months May to August, but is nevertheless appreciably wetter in the mountainous districts of the west than the months of May to July.

The winter months are relatively very dry in

Cambridge, December being drier than June: in this connexion it is of interest to note that Paris lies in a relatively dry area in France as Cambridge and Oxford do in England

The Table V. of normal monthly rainfall, which Dr. Mill quotes from Mr. Salter's book, reveals that though October is the wettest month in England, December is the wettest month in Scotland, Ireland, and Wales. In Ireland, indeed, August is wetter than October. Similarly though April is the driest month in England, May is the driest month in Wales and Ireland and June the driest month in Scotland.

This atlas, which surpasses expectation and arouses admiration the more it is examined, is really as indispensable a part of the ordinary household reference library as a common topographical atlas, but the price is too high it ought to be reduced to 7s 6d or even to 5s, and the book advertised and sold in tens of thousands, instead of in tens.

E. Gold.

## Alpine Studies and Pictures.

- (1) The Natural History of Ice and Snow: Illustrated from the Alps. By Dr. A. E. H Tutton. Pp xvi+319+48 plates. (London. Kegan Paul and Co., Ltd., 1927.) 21s. net.
- (2) The Art and Sport of Alpine Photography.

  Described and Illustrated by Arthur Gardner.

  Pp. 224 + 150 plates. (London: H. F. and G. Witherby, 1927.) 21s. net.
- (1) DR TUTTON'S work on the Alps is a valuable contribution to the literature on ice and snow. It will appeal in particular to those alpinists who have at least a fair general knowledge of physical science and to those others who visit the Alps of Europe with but the common desire to enjoy a holiday there, and at the same time to see and understand the most striking of the developments of snow, ice, and stream in that marvellous country.

For the latter, the chapter to be read as introductory is Chap. viii, "The Call of the Alps," for there the author sets out the attractiveness of his subject with the enthusiasm of a devotee who has himself spent many holidays in the enjoyment of the physical, mental, and artistic pleasures available in the central area of Europe. These are the lure the reader must have in view when he tackles Part I. of the work, for Part I. is for arm-chair evening reading in advance of a spell of freedom.

Part I. (pp. 1-74) gives a very useful résumé of all the major researches which have gone to build up our present knowledge of the chemistry and physics of water, ice, and snow. Successive chapters deal in detail with the chemical and physical relation of water and ice, the crystal structure of ice and snow, the optical, thermal, and electrical properties of ice, its plasticity, viscosity, and elasticity. Throughout this section Dr. Tutton has treated the subject historically, giving the names of successive workers in the direct line of progress, with dates of their work and an outline of their researches and results. This section of the book thus affords the scientific reader an interesting study of the history of the subject from Cavendish in 1783 to the present day

Referring to Part I. in his preface, the author hopes that it "will be readable by any ordinarily educated person." He is, it is to be feared, too sanguine. The person who has to be taught on p 12 the meaning of  $2H_2+O_2=2H_2O$  is not likely to learn by the time he reaches p 42 enough of physical and chemical science to qualify for the study of Sir William Bragg's 1926 work which is there summarised. Yet the matter of Part I is well selected and carefully written. It gives honour to whom honour is due, and should be read attentively by those who have a fair knowledge of physical science. Taken as a whole it is an interesting study in the record of advance in science

Part II. (pp. 75-146) has a short chapter on the geology of the Alps and a longer one on their topography. The latter should be read in company with a good map. The map given is quite unworthy of the book; in fact it is unworthy of this century. Coolidge's "Alps in Nature and History" (1908) had an admirable map (by Bartholomew), and there are now many excellent maps of the region.

Most of the readers of Dr Tutton's comprehensive work will find its kernel in Chaps. xi and xii., snowcaps, glaciers and their movements; crevasses, bergschrunds, and séracs, dirt-bands and veins; moraines and glacier lakes. These give descriptions and explanations of the phenomena which most arrest the interest of travellers in the Alps, and they are freely and well illustrated by photographs which have been carefully selected from a great store. Chap. xii. outlines the history of the "Conquest of the Summits" It affords answers to many questions which every visitor puts to his friends or his guide-book, and its answers are well and fully stated in an interesting manner.

Part III. (pp. 147-304) presents examples of snow and ice forms discussed in earlier chapters. Here, however, they appear as incidentals to a typical set of expeditions. The expeditions selected were chosen for record as affording the most in-

No. 3017, Vol. 120]

teresting illustration of the facts described in the earlier parts of the book, and as being expeditions which the author could describe and recommend from personal knowledge. They are illustrated by 145 pictures on 33 half-tone plates, all being reproductions of the author's own photographs.

These pictures are admirable as illustrations Some are of full-page size, others half-page, but the great majority are six on a page, each of these being about 2 in. ×2 in. Selected with good judgment, they illustrate point after point of interest in the forms of snow and of ice, in the work of frost and of glaciers, and in the scenery produced in the course of prolonged ice action. Each bears definite relation to the text, and the text references to them are complete. Small in size though they are, each makes its point to the eye clearly, yet the execution is such that every one of them stands well the test of detailed examination under a reading lens.

The arrangement of matter in the chapters that deal with definite expeditions is a happy one. It emphasises the individuality of each of the areas traversed and it presents in various settings examples of the different phenomena which in Part II are discussed as types. It is replete with human interest.

(2) In his "Art and Sport of Alpine Photography," Mr. Gardner presents an arresting series of fine photographs—150 plates, six of which have two pictures each, the others are single full-page photographs. These show what can be achieved by skill in the selection of subjects as to each of the many conditions upon which success depends. The author does not, however, leave the pictures and they are pictures—to speak entirely for them-In a light and pleasant running commentary he points to the main factors upon which success depends, and in illustration of the influence of these he refers to the examples in this real album of the Alps which his series of photographs forms. Thus, under "Composition and Foreground" he deals successively with water, trees, rocks, ice, and snow in varied forms. In the following section he deals with weather, lighting, and seasons. In all such matters his work shows that he is exceptionally well qualified to advise those who would produce photographs that are pictures as well as mementoes. In his chapter on mountain portraits, Mr. Gardner points to twenty excellent pictures of the Matterhorn and thirteen of Mont Blanc in illustration of the aspects and moods that go to form what the lovers of a mountain feel as its individuality.

F. G. OGILVIE.

## Our Bookshelf.

Stars and Atoms. By Prof A. S. Eddington. Pp. 127-6 plates (Oxford Clarendon Press; London: Oxford University Press, 1927) 78 6d. net.

This new volume from Prof. Eddington bears the same relation to his "Internal Constitution of the Stars" as does his "Space, Time, and Gravitation" to his "Mathematical Theory of Relativity." It is in the form of three lectures, "The Interior of a Star," Some Recent Investigations," and "The Age of the Stars," with an appendix on the ultimate fate of 'white dwarfs.'

The modern theory of the stars and the way it fits in with and makes use of the modern theory of the atom is a fascinating story, however told But Prof Eddington tells it with the full vigour of a powerful and gifted imagination "Stars and Atoms" is sheer enjoyment in the reading. It is difficult to do justice to the liveliness of his style—the atoms fairly dance before one's eyes—in his own phrase, we see them 'riding sunbeams" His wealth of metaphor is apparently inexhaustible—we have Daedalus and his flying equipment, ballrooms and crinolines, detectives and finger-prints, larders and mousetraps.

Extensive trains of argument are followed through without a mathematical symbol. Prof Eddington is never content with a merely mathematical deduction. He insists that we shall see for ourselves the inwardness of the matter—that we shall not only acquiesce but also give joyful assent. For this reason, and for inspiration's sake, the professional astronomer will profit from this work as much as the general reader. One illustration will suffice. Though not connected particularly with atomic physics, the principle of the Michelson stellar interferometer is described in a way which illumines the whole of optics.

The prospective reader may rest assured that he is not asked to listen to vague speculations. A charm of the book is the author's candidness. Problems are discussed from which present theories are shown to be inadequate. Prof Eddington, a great theorist, shows himself also a disciplined one E. A. M.

Aluminium: the Metal and its Alloys. (A Critical Descriptive Treatise.) By M. G. Corson. Including Chapter on 'Structurography,' prepared in co-operation with J. R. Vilella Pp. xx+291+122 plates (London: Chapman and Hall, Ltd., 1926.) 36s. net.

ALUMINIUM and its alloys are now used very extensively in almost all branches of engineering, and new uses for them are found every year, even in competition with steel. A trustworthy compilation of knowledge concerning them would therefore be of value to the engineer as well as to the metallurgist. This has been attempted by the author of the present work, unfortunately with imperfect success. He has shown great patience and industry in collecting data, but the treatment of

the subject is unsatisfactory, and when information on some point of known technical importance is sought, the statements are too often found to be vague or maccurate. More information as to manufacturing processes would have been welcomed, for such is now to be found scattered through the technical journals, although not as yet systematically collected and reviewed. Diecasting, for example, is used to a far greater extent than would be supposed from the references to it here, and the original difficulties in casting aluminium alloys under pressure have been largely overcome. The imaginary equilibrium diagrams are scarcely a substitute for accurate knowledge, and in fact much more is known of the more important systems than is here indicated. There is much that is of value in the book, and the experienced metallurgist will make critical use of the tables of physical and mechanical data. The photo-micrographs at the end of the volume are of excellent quality, and illustrate the immense improvement in the technique of preparing these rather difficult alloys for the microscope which has occurred in the last year or two

Primitive Man: his Essential Quest. By Dr. John Murphy. Pp. xiv +342. (London: Oxford University Press, 1927) 15s net

THE primitive in man in Dr Murphy's definition is that which characterises him near to his origin as man, that is, when he began to be human, and includes the mind of the savage of the present day who is at a low stage of culture, probably at the intellectual level occupied by early man. His viewpoint in analysing the development of human society from its beginnings in primitive customs and belief to higher manifestations is evolutionary and psychological. In his view, man has progressed by integration through differentiation from the lower to the higher on a line which in a sense is parallel to the evolution of the brain. This, as has been shown by the study of the brain in the anthropoids and fossil man, has been a process of development in the frontal area and a resulting improvement in the powers of co-ordination which have been largely responsible for man's intellectual advancement. Dr. Murphy therefore has a sound physical basis upon which to rest his interpretation of the facts; but it needs no great discernment to see that from the outset he is at odds both with the diffusionist school of Prof. Elliot Smith and with the recently enunciated theories of Prof Levy Bruhl.

A Treatise on Light. By Dr R. A. Houstoun. Fifth Edition. Pp. xi+489. (London: Longmans, Green and Co., Ltd., 1927.) 12s. 6d. net.

The fact that this book has had a new impression or new edition every two years since 1919 is sufficient evidence of its use to teachers and students and of their appreciation of it. The author is to be congratulated in that he has not burdened the student by the introduction of accounts of recent advances in kindred branches of the subject. His

final chapter might well have been omitted, the one valuable addition on the angular diameter of stars being inserted in the chapter on interference. The rest is out of place in the book and in any case could not fail to be inadequate.

An account of modern apparatus for the determination of indices of refraction would have improved the chapter on that subject, and in the chapter on diffraction the accounts of the Lummer-Gehrcke and Fabry-Perot interferometers should have been given in more detail both in theory and practice. The theory would follow very readily from the excellent treatment of diffraction given in this chapter. These are, however, slight criticisms of an excellent treatment of the subject. The reader cannot fail to appreciate the careful mathematical presentation, which is well exemplified in the chapters on lenses, diffraction, and on the nature of light.

The Autobiography of Kingsley Fairbridge With a Preface by the Rt. Hon. L. S. Amery and an Epilogue by Sir Arthur Lawley Pp. x+188. (London: Oxford University Press, 1927.) 6s. net.

KINGSLEY FAIRBRIDGE had an active and adventurous life before he went to Oxford as a Rhodes scholar. Most of the book consists of those early experiences, and gives an admirable picture of Rhodesia in the making. But the importance of the book lies in his scheme of Imperial settlement. Fairbridge was convinced that the solution of the unemployment and emigration problems of Great Britam were to be found in taking children from the large towns and training them in schools in the Dominions to become farmers. His enthusiasm led to the foundation at Oxford of the Child Emigration Society In 1912 he started his farm school in Western Australia. There were many difficulties to be contended with, of which the financial was not the least, but before Fairbridge died in 1924 the scheme was on a sound footing. The book is a worthy record of a man of far-seeing

The Student's Handbook of British Hepatics. By Symers M Macvicar. Second edition, revised and enlarged. Pp. xxxi+464+viii. (Eastbourne: V V. Sumfield; London: Wheldon and Wesley, Ltd., 1926) 24s. net.

THE value of an accurate systematic treatise in stimulating interest in a group is evidenced in the call within a comparatively short time for new editions. Lister's "Mycetozoa," Dixon's "Mosses," and Lorrain Smith's "Lichens" are familiar examples, and to these have now been added Macvicar's "Hepaticæ." The accurate descriptions, useful keys, and excellent illustrations for every species at once made the work invaluable to students, and after fourteen years the stock has been exhausted. The new edition includes only mmor changes; a few additional species, changes in rank of certain forms, and a full glossary being the most important.

## Letters to the Editor.

## The 'Forbidden' Line of Mercury at \2270 in Absorption.

In a letter to NATURE of May 28, p. 778, I stated that the line  $\lambda 2270$  which is 'forbidden' by the selection principle for inner quantum numbers, could not be observed in absorption. I have now repeated the attempt with a more powerful instrument, which has been placed at my disposal by a grant from the Council of the Royal Society. A definite positive result has been obtained, the line showing up clearly in absorption by a column of mercury vapour 45 cm. long boiling at a pressure of It is well seen on several different negatives. The range of conditions for observing it is very limited. Too much vapour blots out the continuous background; too little fails to show the line absorp-

The observation seems of considerable theoretical interest, as showing that direct transition from the normal to the metastable excited state of the mercury atom can sometimes occur, even though very rarely. The resonance line of mercury,  $\lambda 2537$ , would. I believe, show up in comparable intensity with the same column of mercury vapour at the atmospheric temperature; thus at about one millionth of the density used for  $\lambda 2270$ .

RAYLEIGH.

Terling Place, Chelmsford, Aug. 10.

## Prof. Labbé's Copepod 'Allomorphs.'

Prof. Labbé, in the succession of papers in which he has expounded his theory of allelogenesis, claims to have established as a fact that, in the salines of Croisic and in the aquaria of his laboratory, an evolution of Copepoda has been observed, leading through a series of eight stages from Canthocamptus to Cyclops. According to his theory, the eggs laid by one species of Harpacticid may produce 'allomorphs' which, according to accepted standards of classification, would be considered to represent distinct genera or even families If such were indeed the case, and it were possible in seven years to observe the transformation of Canthocamptus into Cyclops, it would indeed be necessary for systematists to abandon their task ın despair.

Those who are not specially conversant with the detailed systematics of the Copepoda will appreciate the position more clearly if it were stated in terms of a more familiar group. One may, I think, quite fairly say that it would be much less surprising if the egg of a sparrow were to produce a robin, and the robin's egg a swallow, than if the eggs of a Cantho-camptus gave rise to Wolterstorffia and those of the latter to Copepods having the characters ascribed to Ferroniera. Such revolutionary results are obviously inacceptable, and should not even be considered, unless supported by the most scrupulously exact descriptions and experimental evidence. Prof. Labbé in his most recent paper (Arch. Zool. Exp. et Gen., 66, pp. 135-290; 1927) states (p. 246), "Nous avons maintenant une sériation complète de stades qui donne la preuve de l'arbre généalogique. C'est cette preuve qu'apporte le présent travail," so that

we may suppose that he has now offered all the evidence which he is prepared to give. I have already (NATURE, Sept. 4, 1926) given some reasons why such evidence as he has previously offered is insufficient, and it is only necessary to consider that which is now brought forward.

First, with regard to the descriptions of the 'species' with which Prof. Labbé deals A detailed discussion of each of these would be a long and tedious business and, for reasons which I shall give, it is scarcely practicable or necessary, but one or two cases must

Prof. Labbé does not appear to have availed himself of the most indispensable systematic work on Copepods, Prof Sars's "Crustacea of Norway." Had he done so he would scarcely have redescribed Metis ignea Philippi under the new name of Parametis sanguinea. That the two are identical there can be no doubt, and a comparison of his figures with those of Sars will give some gauge of the accuracy of Labbé's figures in general.

The original parent form of the experimental cultures from which were derived in "huit étapes successives" Wolterstorffia croisicensis, Ferroniera mirabilis, F. cyclopoides, Regis servus, Herouardia paradoxus. Cyclops phaleroides and C. serrulatoides, is called Canthocamptus salinus. This is the species named in previous papers C. minutus O. F. M., but Labbé has recognised that the original identification was unfounded (p. 209). A short description and some figures of this parent form are given which require comment In the first place, the 1st antenna of the female is stated to be of seven "très courtes" joints, but it is figured (Fig. 41) as of seven unusually long joints, the fifth of which bears an æsthete. It may safely be said that this is not the antenna of a Canthocamptus, and indeed I am not aware of any genus or family of Copepod to which it could possibly be referred. Secondly, the first leg of the male and female are shown entirely unlike, and in neither case with an inner seta on the 2nd joint of the exopod I do not know of any Harpacticid showing such an extraordinary sexual difference, and, if the figures are correct, it is quite clear that the animal is not a Canthocamptus, and that two species have been confounded in one description. What these may have been it is impossible to suggest. There is reason also to suppose that the same error, namely, that of giving figures and drawing up descriptions from different species and uniting them under one name, has given rise to others of the remarkable forms here dealt with. It would not be difficult to produce some very striking new creatures by such combina-

If Fig. 103 of the 2nd antenna of Ferroniera cyclopoides male be compared with Fig. 117 of the same appendage of Rhynchoceras rota, a strong suspicion is aroused that in this case the same male has been attached to both species. The appendage as figured is so extraordinary that it could scarcely be identical in two species of different genera. The sexual difference in this appendage is, so far as I know, a new discovery by Prof. Labbé.

It is possible, in some cases, to suggest or to affirm the identity of some of these new species with others already known, but it is not worth while discussing

them all in detail:

(1) The genus Portierella is very extraordinary, and the two species of it in some respects so unlike that they cannot possibly be congeneric if the figures are correct. It seems probable that there is a mixture here too, and that some species of Tisbe forms part of it.

(2) Rhynchoceras rota may, in part, be Tachidius

brevicornis. R elongatus is certainly Euterpina acutifrons, but the "lst gnathopod" does not seem to belong to it

(3) Regis servus is Wolterstorffia confluens Schmeil. It is possible that R racoutzar may be W blanchardi

(4) Herouardia paradoxus certainly includes Halicyclops magniceps, but some of the figures cannot be correct. For example, in no known Copepod is there an exopod on joint 3 of the 2nd antenna, and leg 1 (Fig. 176) has some quite unique characters. Labbé lays great stress on the presence of a spiny operculum in his new species, and, if it actually existed, it is, of course, impossible that he could have been dealing with H. magniceps. On the other hand, he figures it (Fig. 174) on the ventral side and attached to the fourth abdominal somite—a quite impossible situation

(5) Mesquieria cærulescens is Acartia latisetosa

Kric.

It appears, then, that reliance cannot be placed on the accuracy of Labbé's descriptions and figures. Further, if he has in some cases confounded two or more species in one description, it seems that the whole edifice of theory which he has built on his facts must crumble, for the succession of forms on which

it is based disappears.

With regard to the reliability of the experimental methods, it does not seem necessary to say much since (p. 211) Labbé himself admits that no attempt has been made to prevent contamination of the cultures by the introduction of extraneous nauplu. He disposes of this difficulty simply by saying that his interpretation is more probable than that species should always have been introduced in the same order, and by the statement that the allomorphs always appeared in his cultures long before they were "generated" in the salines. On the other hand, we are not told anything about the number of cultures in which this order of succession was observed, or indeed anything whatever about these observations. so that it is impossible to weigh the probabilities. It is very necessary to know more about them. For example, these Harpacticids are minute creatures creeping about in mud and vegetation, and in any culture in which they would be able to thrive it would be most difficult to remove and examine the whole population. They can seldom be recognised except under high powers of the microscope, and without examining the whole, or at least a large part, of the population of an aquarium, it would be rash indeed to say that all the individuals belonged to one species. A very small aquarium stocked as Labbé's seem to have been stocked might readily contain half a dozen species, and it might involve a lengthy examination before all of them were dis-The Harpacticids provide peculiarly bad material for an investigation of this kind.

It is most remarkable that the salines of Croisic should contain only an assemblage of new species and genera and lack so many that are characteristic of such places. For example, no species of Amphrascus is mentioned; no Tachidius; no Mesochra and no Stenhelia. Labbé's identification of Nitocra hibernica is obviously wrong, and there can be little doubt that other species of this genus actually occur. As I have pointed out above, some of these genera were probably actually present and have been described

under other names.

Almost every page and paragraph of this paper provokes criticism, but it seems scarcely worth while to pursue the subject further or to deal with Labbé's views on the systematics and comparative morphology of the Copepoda. They need not be taken seriously. The only question which concerns zool-

ogists is whether or not species at Croisic are giving use by allelogenesis to new species or genera. If this paper contains all the proof which Labbé is prepared to offer, one can say with complete certainty that there is no substantial evidence that such is the case.

ROBERT GURNEY.

Ingham, Norwich, Aug. 3

#### Ectoplasmic Matter.

A PROTEST should surely be made against the statement of the reviewer on page 111 of Nature for July 23 that "various kinds of . . ectoplasmic formation are facts of experience" The number of persons, among those competent to form an opinion, who are of this belief, must be a very small minority, and the supposed existence of ectoplasm is no more proved than that of any other psychic phenomenon

One of the proofs of the existence of ectoplasm relied upon by Dr. Geley in the book to which the review refers are wax masks of spirit hands. As has recently been shown by Sir Arthur Keith and others, these can easily be counterfeited, wax being a substance that readily becomes plastic and capable of fraudulent manipulation at quite low temperatures.

I have, therefore, elsewhere recently made the suggestion that these masks would be more conclusive if made, say, in cast-iron or some other metal which is rigid and nonplastic at ordinary temperatures, but I fear that ectoplasm would frizzle just as easily as the living hands of the mediums or of their confederates, which, I am convinced, are the real agents involved.

A. A. Campbell Swinton

The complete sentence in my review was must now be admitted that the various kinds of lucidity and of ectoplasmic formation are facts of experience as actual, though as sporadic, as hypnotism, insanity, or physical deformity "Mr. Campbell Swinton's protest is interesting, because it seems to mply that all facts of experience must be scientific facts and, inversely, that all scientific facts are common facts of experience. The gist of the review, as well as my previous communications on psychic phenomena (Oct 23, p. 588, and Nov. 13, 1926, p. 693), is to the effect that no 'proof,' in the strictly scientific sense, has been obtained of any supersensible phenomenon. Many 'facts of experience' cannot be explained as yet by exact science, which requires a formula so that the experience may be repeated or prevented at will. Again, much of the phenomena of scientific laboratories are not general facts of experience and are accepted credulously and without understanding by the lay majority. Such common facts of experience, known to the majority as disease, deformity, dreams, and insanity, are admitted to be actual, but they do not, therefore, come under exact science, since the laws underlying these states of matter have not been clearly, that is scientifically, defined. Science has advanced and will continue to advance by discovering the laws underlying all facts of experience, thus bringing the latter under self-conscious control.

Uncommon facts of experience, known only to the minority, are not readily admitted by the majority, for the very good reason that experience is an individual matter. To 'believe' in the reality of another's experience one must have had an analogous experience unless one understands the laws behind or is an undeveloped, credulous person. This is a beneficent law of individual development, and a protection against superstition and charlatanism. On the other hand, we cannot believe that all those who have had experiences unknown to ourselves are fools or knaves.

The man who never dreams does not deny that others

have had such experiences.

It seems to me the duty of science either to show that, in the nature of things, there is no inherent possibility for the existence of ectoplasmic matter, or to attempt a tentative explanation of the phenomena. Blank denial is a foolish policy in the face of rapidly spreading superstitions—spiritistic and religious—amongst the people, many of whom are reacting against the materialistic attractions science has brought within easy reach of the democracy. If the human race is to advance in self-knowledge, science must maintain its authority. What is now termed ectoplasmic matter has always been a concomitant of mediumistic materialisations, and tests suggested to prove its existence are unscientific, for the function of science is not to prove the existence of phenomena, but, when admitted, to investigate and explain it. The first step toward the scientific elucidation of psychic phenomena (and the exposure of superstitious beliefs) is to admit them as facts of experience amongst certain peculiarly organised w. W. L.

# Occurrence of Extensor Rigidity in Quadrupeds as a Result of Cortical Injury.

PERMANENT contraction of certain muscle groups occurs in apes, following the removal of the cortical motor centres of the lumbs. Hermann Munk (1895) stated that 'contractures' do not occur in rabbits, cats, and dogs following similar operations. Recent workers are of the opinion that extirpation of the gyrus proreus of the cat results in an exaggerated extensor tonus in the contralateral limbs, but removal of the motor cortex fails to influence the tonus of the

corresponding limbs.

I observed that removal of the cortical limb areas in cats results in extensor rigidity in the contralateral fore- and hind-leg. If the foreleg area alone is removed the rigidity is confined to the contralateral foreleg; also if the hindleg area alone is removed the rigidity is confined to the contralateral hindleg. In chronic preparations the rigidity has been observed six weeks after the operation. Injury to or removal of the gyrus proreus in cats, in my experiments, does not result in an increased extensor tonus in the contralateral limb muscles, but there is a definite stiffness in the neck muscles.

Extirpation of the foreleg area in rabbits and guinea-pigs results in a marked extensor rigidity in the contralateral foreleg. In chronic rabbit preparations, rigidity has been observed two weeks after

the operation.

The rigidity observed in the animals studied has certain definite properties. It appears very quickly following the operation on the cortex, in the limb muscles which oppose gravity. It can be temporarily inhibited by stimulating reflex movement (flexion reflex and progression). In certain positions (dorsal decubitus) the rigidity exists over long periods of time with no apparent fatigue. In rabbits and cats, labyrinthine and neck reflexes, as described by Magnus and De Kleijn, influence the rigidity in a manner similar to that observed in decerebrate preparations.

It would appear, then, that the rigidity observed in these experiments is due to a release from cortical control and that it is similar to the decerebrate

rigidity as described by Sherrington.

## Etiology of European Foul-brood of Bees.

SINCE Cheshire and Cheyne investigated the cause of foul-brood of bees in England and attributed the etiology of the disease to B. alvei, which is almost invariably found in large numbers in infected larvæ, much work has been done to corroborate their results. In no case, however, has an isolated culture of B. alvei been known to produce the disease. On the other hand, G. F. White and others have refuted the claim of Cheshire and Chevne and ascribed infection in this disease to B. pluton. Owing to their inability to cultivate and isolate the organism, however, their claim has remained hypothetical; for it could not be determined whether this organism was itself merely a secondary invader—as they said was B. alvei—or whether the infection was mixed, or whether, indeed, these organisms played any pathological rôle in the

It has been my good fortune, however, to develop a medium admirably suitable for the growth of *B. pluton* (White). A 0·15 per cent. concentration of agar, together with certain nutrients, is employed as an enrichment medium; and a concentration of 1·5 per cent. agar for the isolation of the organism at 37° C. By this method pure cultures of *B. pluton* can be readily obtained, provided the larvæ used contain a preponderance of this organism.

I have obtained infection in a healthy colony of black bees in four days, using as inoculum cultures of the organism derived from isolated colonies. The symptoms of the diseased larvæ accorded with those observed in naturally infected larvæ, and the microscopical picture was typical—B. alvei forms being also present, though only in small numbers. The organism

has been re-isolated successfully.

Morphological studies thus far suggest the identity of the two organisms. While the results in this are not yet complete, cultures of *B. pluton* have been observed to change to *B. alvei* form, resembling biologically the *B. alvei* isolated from infected larvæ. This further corresponds very closely with the changes observed in brood naturally infected, where the ratio of *B. alvei* to *B. pluton* generally increases as the putrefaction of the larvæ progresses, so that *B. pluton* is almost eliminated. The more conclusive substantiation of this is anticipated, and its accomplishment should lead to the demonstration of important relations between the pathogenicity of micro-organisms and their life stages.

Denis R. A. Wharton.

## Mediterranean Oligochæts.

As our knowledge of the Oligochæta of the Mediterranean is far from being exhaustive, the following records of finds made in Corsica and the Maritime Alps in April last may be of service to future investigators.

1. Microscolex phosphoreus (A. Dugès). Stiff loam, Ville-franche, about 200 ft. Already found in

Sardinia.

2. Enchytræus sp.? Peira Cava, 5000 ft., among the snow; species not yet determined.

3. Eiseniella tetrædra (Sav.). The typical form taken at Thouët (Touët), April 20, and Calacuccia,

Corsica (height, 847 m.), April 27.

4. Eisenia alpina (Rosa). Peira Cava, as before, in perfect condition. On April 2, 1910, I received one specimen from Mr. Wm. Evans, collected in Perthshire. This is at present the only British record; previously reported as occurring in Switzerland, the Piedmontese Alps, Armenia, and Syria.

5. Dendrobæna rubida (Sav.). Peira Cava; one beautiful specimen of this well-known tree-worm.

6. Allolobophora caliginosa (Sav.). Thouet, in a streamlet with Eiseniella as above The same species as the next, but with modifications in the girdle.

7. Allolobophora trapezoides (A. Dugès). In the stream at Calacuccia with Eiseniella.

8. Lumbricus castaneus (Sav ) By stream Thouet, April 20. All the foregoing are British. By stream at

I found a worm (probably A. caliginosa) at Lucéram, but it retreated into a rock-crevice before I could secure it, and so was lost. As my object was to explore the Alps, no time was devoted to the examination of the lowlands and seashore, where, doubtless, a considerable number of species might be discovered, both in Corsica and in the Riviera. Worms are used for angling in Corsica, but no one has determined the species ("The Impossible Island," 82).

HILDERIC FRIEND.

Solihull, July 25.

#### The Tetrad Difference Criterion.

In recent years the quantity F, called the 'tetraddifference', has become very important in psychological investigations as to the possible nature of the underlying causes of mental activities. If there are four such activities, and  $r_{13}$ ,  $r_{24}$ , etc., the six correlation coefficients, F is defined by the equation  $F = r_{13}r_{24} - r_{14}r_{23}$ . The value of F, in practice,

approximates to zero.

On the assumption that the activities are due to the operation of a number N of 'all or none' factors, and that the four activities in question involve the operation of the fractions  $p_1, p_2, p_3, p_4$  of these factors respectively, the most probable value of F is zero, but it is important to know how far we may, a prior, expect it to deviate from zero. In other words, if every possible arrangement of the  $p_1N$ ,  $p_2N$ ,  $p_3N$ ,  $p_4N$  factors out of the universe of N factors be considered, and the tetrad-differences F calculated, we require the standard deviation of F. In the course of investigation the following results have been arrived at theoretically, and without approximations: (1) The mean value of F is zero.

(2) The standard deviation of  $F = r_{13}r_{24} - r_{14}r_{23}$ , calculated on the above assumptions, is given by

$$\begin{split} \sigma_{F}^{2} &= \frac{1}{N-1} \bigg[ \ 4p_{1}p_{2}p_{3}p_{4} \\ &- 2(p_{1}p_{2}p_{3} + p_{1}p_{2}p_{4} + p_{1}p_{3}p_{4} + p_{2}p_{3}p_{4}) \\ &+ p_{1}p_{3} + p_{2}p_{4} + p_{1}p_{4} + p_{2}p_{3} \\ &+ \frac{2(N-2)(p_{1}-1)(p_{2}-1)(p_{3}-1)(p_{4}-1)}{(N-1)^{2}} \bigg]. \end{split}$$

If N be supposed large, and we put the p's each equal to their average p, we have, as an approximation.

$$\sigma_F^2 = \frac{1}{N} \cdot 4p^2(1-p)^2$$
.

JOHN MACKIE.

The University, Edinburgh, July 16.

## The Spectrum of Gold Chloride.

VAPOUR from auric chloride (AuCl<sub>3</sub>) was introduced into a stream of active nitrogen. The observed spectrum consisted of intermingled green bands, shaded toward the old. shaded toward the red. The strongest band heads were measured and found to comprise two systems given by the formulæ:

No. 3017, Vol. 1201

A 
$$\nu = 19113 \ 8 + 312 \ 0(n' + \frac{1}{2}) - 382 \ 8(n'' + \frac{1}{2}) - 0.70(n' + \frac{1}{2})^2 + 1 \ 30(n'' + \frac{1}{2})^2.$$
B.  $\nu = 19238 \ 3 + 316 \ 3(n' + \frac{1}{2}) - 382 \cdot 8(n'' + \frac{1}{2}) - 1 \ 45(n' + \frac{1}{2})^2 + 1 \ 30(n'' + \frac{1}{2})^2.$ 
(Half-quanta were not required for the accuracy of the latest that the stress used in raws of the latest decrease.

these data, but were used in view of the latest developments.) The identity of the coefficients of terms in n'' shows a common final vibrational level which is probably the normal state of the aurous chloride

(AuCl) molecule.

Associated with each of the strong heads in the two systems were weaker heads corresponding to AuCl<sup>37</sup>, taking the stronger heads to be due to AuCl<sup>37</sup>, taking the stronger heads to be due to AuCl<sup>35</sup>. In this molecule, for the isotopes of chlorine,  $\rho = 0.9768$ With the dispersion employed (around 28 Å.U. per millimetre), the isotopes of gold were not evident,  $\rho$  for this case being 0 9992. Gold lines at wave-lengths 4792 6, 3122 8, 3029 2, 2748-3, 2676 0, 2641-5, 2428 0, and 2352 7 Å.U. also appeared from excitation of this salt by active nitrogen. The intensities of the band heads in each system follow the usual distribution with changes in n' and n''. In the region 7000 to 2000 Å.U., no other spectrum from gold chloride appeared.

New York University, Washington Square College, Washington Square, New York.

#### 'Oertling' Balances.

It is generally admitted that there are few finer craftsmen than the London instrument maker. As employers, therefore, we regret to find a continental

origin ascribed to any of his products.

Since 1849, when the late Mr. L. Oertling settled in London and commenced business as a builder of precision balances, instruments have borne the mark 'L. Oertling—London,' which has, in fact, become known throughout the world as denoting the highest grade of workmanship in this very specialised

It is easily understood that the name might suggest to some a foreign origin; but the truth is that this has never been a foreign firm with a London address, or a firm importing foreign balances, or parts for

Every 'Oertling' balance has been built throughout in London; and, since we find misapprehensions on this point, we wish to stress that our output is entirely British—the product of British brains, British craftsmen, and British capital. MALCOLM DUNBAR,

L. Oertling, Ltd., Turnmill Street, London, E C.1, Aug. 6.

## Petrified Forests.

The interesting note in your number for August 13, p. 239, arising out of Miss Wimfred Goldring's article on the Upper Devonian Forest of Gilboa, N.Y., suggests that readers of NATURE may like to know of the stump of one of these Pteridosperm trees, Eospermatopteris textilis, which was very kindly presented to the British Museum by Mr. Hugh Nawn, president of the Hugh Nawn Contracting Company, and found during the company's work of building the Gilboa Dam. Mr. Nawn informs me that this specimen, and one that he has sent to the National Museum of Ireland, are the only specimens outside the United States.

F. A. BATHER.

(Director).

British Museum (Natural History), S.W.7, Aug. 13.

## Canadian Hydro-Electric Power Development.

By Dr. Brysson Cunningham.

DURING a recent tour in Canada the writer, who had on a previous occasion seen Niagara and the Chippewa-Queenston installation, was able to investigate more widely, though admittedly in a superficial manner, the present stage of hydroelectric power development in the province of Quebec, where he visited power-sites and waterfalls at Shawinigan Grandwing Le Cabella and Mont

Quebec, where he visited power-sites and waterfalls at Shawinigan, Grandmère, La Gabelle, and Montmorency. He also took the opportunity of discussing the situation with officials of the Shawinigan Water and Power Company at Montreal and of the

Water Power Branch of the Department of the

It has been computed that there is some eighteen and a quarter million horse-power of 24 hours availability, and 80 per cent. efficiency, at ordinary minimum flow, in the whole of Canada. Of this, nearly twelve million hp., or say two-thirds, is located in the provinces of Quebec and Ontario, the former having the preponderant share of seven million hp. If the figures be referred to the basis of ordinary six months flow, the total for the Dominion is raised to 32 million h.p. and the proportions of Quebec and Ontario are 11,640,000 h.p and 6,808,000 h.p respectively. The actual water-wheel realisation is fully thirty per cent. in

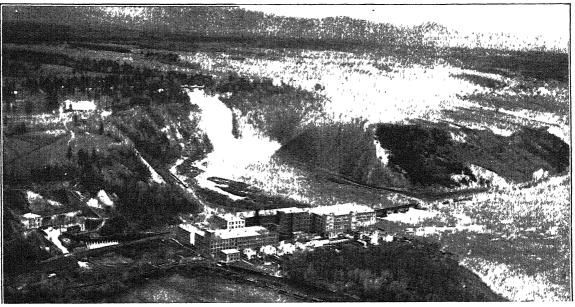

Photo.]

[Fairchild Aerial Survey Co (of Canada), Ltd.

Fig. 1.—Montmorency Falls and Power Station. The Falls are 274 ft high; 114 ft more than Niagara. Reproduced by permission of the Shawingan Water and Power Co.

Interior at Ottawa. The following notes of his observations, combined with information obtained from official sources, may be of interest to readers of Nature

The vital importance of water power to Canada in the development of its industries is a fact not readily appreciated in Great Britain, where water power supplies are relatively of negligible proportions and an abundance of coal for steam driven plant fully compensates for the deficiency. In Canada, the reverse is the case; or rather, to speak with greater precision, it is the case in the more highly developed and most populous provinces of the Dominion, namely, Quebec and Ontario. Neither of the provinces in question is favoured with coal deposits; at any rate, none of economic value has been found, or seems likely to be found: on the other hand, both have numerous waterfalls, most of them capable of development as sources of power at a reasonable and remunerative outlay.

excess of this. These figures give some idea of the vastness of the resources available, especially when compared with the mere million h.p. which represents the total estimated resources of the British Isles. It must not be assumed that the figures, however, are in any sense complete. Indeed, they represent the minimum possibilities. Many rapids and falls in Canada, of greater or lesser power capacity, are scattered over rivers and streams which are not yet recorded and can only become available for classification as detailed survey work is extended and carried out. This is particularly true of the less explored northern districts of the Dominion. Moreover, full consideration has not yet been given to those power concentrations which may be feasible in rivers and streams of moderate gradient with the aid of dams and impounding works. Altogether, it must be admitted that the natural water resources of Canada are of a very high and even stupendous order, amounting on a conservative estimate to fully forty million horse-

Out of the impressive total, whatever it may be, so far the actual utilisable turbine installations established at the present time yield only 41/2 million h.p.—a very small proportion, barely eleven per cent. of the total.

It may be of interest here to insert a full table of the estimated provincial distribution of water power as corrected up to Jan. 1 last, and issued by the Water Powers Branch of the Canadian Department of the Interior.

AVAILABLE AND DEVELOPED WATER POWER IN CANADA (JAN. 1, 1927).

	Available 24-h 80 per cent.	Turbine	
Province.	At ordinary min. flow (h p.).	At ordinary 6 months flow (h p ).	Installation (h.p).
British Columbia Alberta Saskatchewan Manitoba Ontario Quebec New Brunswick Nova Scotia Prince Edward Island Yukon and Northwest Territories	1,931,142 475,281 513,481 3,270,491 4,950,300 6,915,244 50,406 20,751 3,000 125,220	5,103,460 1,137,505 1,087,756 5,769,444 6,808,190 11,640,052 120,807 128,264 5,270 275,250	460,562 34,107 35 227,125 1,790,588 1,915,443 47,231 65,702 2,274 13,199
CANADA	18,255,316	32,075,998	4,556,266

The value of the  $4\frac{1}{2}$  million h.p. already developed may be gauged from the fact that it is found that each installed h.p. is capable of effecting an annual saving of 6 tons of coal, or a total of 27 million tons of coal per annum. With the increasing economies which are taking place in the production of power from coal, this valuation of 6 tons per h.p. will no doubt require adjustment from time to time, but at present it represents a fair and reasonable equivalent. To the provinces which have to import their coal for industrial purposes, the economy is of significant proportions.

It is scarcely to be wondered at, in these circumstances, that the exploitation of available water power sites in Canada is proceeding steadily and even rapidly. To give one example only, five years ago (on the occasion of the writer's previous visit to Canada) the River Saguenay, running from Lake St. John to the River St. Lawrence, was a natural, unregulated stream, flowing through a remote and primitive district. In the interval, some 450,000 h.p. has been developed at Isle Maligne, a station on the river where a fall of about 100 ft. has been utilised, and preparations are now in hand to instal a second power house at Chuteà-Caron, where the fall is 200 ft., with a corresponding availability of power. Works and mills are springing up along the banks, and a new industrial town is projected at Arvida.

During last year (1926) the total horse-power installed throughout the whole of the Dominion was 265,838, but while this is a substantial figure in itself, it fails to take into account many constructional activities which had not reached their final stage. A number of these are nearing completion and will shortly add 1,700,000 h.p. to the Dominion total, while others in active prospect indicate a further addition of at least one million h.p. The capital invested, or involved, in these undertakings cannot be put at a less figure than

270,000,000 dollars.

That progress in the future is likely to be accentuated may be inferred from the consideration that,

DEVELOPED WATER POWER IN CANADA.

Column 2 includes only hydro-electric stations which develop power for sale.

Column 3 includes only water power actually developed by pulp and paper companies. In addition to this total, pulp and paper companies purchase from the hydro power central stations totalled in Column 2, horse power estimated at about 425,000 h p., making a total of about 951,000 h p. actually used in the manufacture of pulp and paper.

Column 4 includes only water power actually developed in connexion with industries other than the central station and pulp and paper industries. These industries also purchase blocks of power from the central stations totalled in Column 2.

Column 5 totals all turbines and water wheels installed in Canada.

Column 6, population at June 1, 1928, as estimated by the Dominion Bureau of Statistics.

Column 7 averages the developed water power per 1000 population.

as stated in the Government Report dated Mar. 1 last, the consistent earning power of the various hydro-electric organisations, coupled with the fact that the output of new stations is absorbed almost as soon as it comes on the market, has created a favourable impression in capitalist circles and established a public confidence which is demonstrating itself in the inception of wider and more expansive undertakings. Of the 265,837 h.p. installed during 1926, more than 219,000 h p. was destined for public distribution through the medium of central electric stations. Pulp and paper mill organisations installed 44,760 h.p. during the year, mainly connected to electric generators, and they will purchase a considerable portion of the additional installation of the central electric stations. Installations other than for central electric station purposes and in pulp and paper mills, totalled only 2072 h.p., of which 2000 h.p. was for electrochemical reduction.

The uses to which the existing installations throughout Canada are put, indeed, continue to

follow on general lines the apportionment in the foregoing paragraph. Preponderant, and of growing importance, is the distribution of hydroelectricity through the medium of central electric stations, which account for fully 80 or 81 per cent. of the total. Next comes the pulp and paper mill industry, absorbing about 11½ per cent. of the total power, apart from the large purchases which the mills make from the central stations themselves General industrial enterprises, such as electrochemical reduction, lumber manufacturing, flour milling, grain grinding, water pumping, etc., account for the balance of 7½ per cent.

The table above from the Government report is of interest in showing these allocations, and also the total hydraulic installation per thousand of the population, a feature which bears on the capacity for industrial output of the workers of the Dominion The high average of 485 h.p. per 1000 population enables Canada to assume a position of importance among the nations of the world in per capita utilisa-

tion of water power.

## Some Colouring Agents in Glasses and Glazes.1

By Sir Herbert Jackson, K.B.E, F.R.S.,

Director of Research, British Scientific Instrument Research Association.

BEFORE dealing with the colours and effects produced by ferric oxide in glasses and glazes, let me direct attention first to the different shades of colour which can be seen in varieties of the oxide itself. These range from a reddish yellow through brick reds, bright reds, to a rich brown red and almost to a black. Some specimens also have almost a bronze-like appearance. The range of colours produced when ferric oxide is used as a colouring agent for glasses and glazes is practically as great. It is doubtful if the colours produced by ferric oxide are due to compounds of this oxide with the other constituents of the glass. Without going into elaborate detail it is somewhat difficult to give adequate support to this statement. Perhaps the simplest way of dealing with it is to take the behaviour of ferric oxide in lead glasses, frequently described as flint glasses. There are light flints and dense flints. In the light flints there is always a notable quantity of an alkali such as potash or soda along with the lead oxide. In the dense flints the proportion of alkali is decreased and the proportion of lead oxide is increased.

Now, taking three such glasses as examples, having specific gravities of 3.2, 3.8, and 4.8, it is possible to add a known, but small, quantity of ferric oxide to the first glass and still to produce a glass having no detectable yellow colour to the eye. The same amount of iron added to the second glass will give a noticeable yellow colour, and added to the third glass will give a marked yellow colour. The glass of specific gravity 3.2 contains a notable proportion of alkali, and there is reason to believe that this either promotes the formation of a compound of ferric oxide with the alkali or the

<sup>1</sup> Continued from p. 266.

formation of a double silicate, either sodium ferric silicate or potassium ferric silicate; such compounds appear to be colourless. If the quantity of iron be increased, then a colour can be produced in the light flint, and, by increasing the percentage of ferric oxide to 5 per cent., a fairly strong yellow colour is produced. With 10 per cent. of ferric oxide in the same glass the colour is a deep brownish red when looking through a thickness of about 3 mm. With 20 per cent. of ferric oxide an even richer red colour can be seen when looking through a thickness of ½ mm.; but in thicknesses of 1 mm. or more the glass is practically opaque. When the percentage of iron is raised much higher, some ferric oxide crystallises out from the glass on cooling, and with 40 per cent. of ferric oxide the small crystals dispersed through the glass can be seen with a hand lens. With the denser flints, containing a lower percentage of alkali, colours similar to those described above are produced with much smaller proportions of ferric oxide.

A reasonable explanation of this would be on the same lines as the suggestions made in dealing with cuprous oxide and metallic copper, namely, that the light yellow colour is due to a small amount of free ferric oxide dispersed in the glass as extremely fine particles; the transparent deep yellows and brownish reds would represent a greater concentration of ferric oxide similarly dispersed, possibly also, as the percentage of ferric oxide gets higher, as somewhat larger particles. In the 20 per cent. glass mentioned the particles are still too small to be seen, but in specimens of lead glass containing nearly 30 per cent. of ferric oxide, fine clouds of almost irresolvable particles can be seen in the microscope.

Leaving the subject of lead glasses coloured with

ferric oxide, I would first mention the behaviour of ferric oxide in a glass containing a large proportion of phosphoric acid, an acid which in glasses may be described as a much stronger acid than silica. Ferric phosphate is a definite compound and is colourless, in this phosphoric acid glass, quite a notable proportion of ferric iron may be present without showing any colour. Evidence that the iron is in the ferric state is obtained by heating the glass in a highly reducing atmosphere; this reduces the ferric iron to the ferrous state, and the glass is found to have developed a marked indugo blue colour, due, possibly, to ferrous phosphate, or to ferrous phosphate along with a very small proportion of unreduced ferric phosphate.

In such glasses as ordinary sodium calcium silicates, it is rather difficult to obtain light pure yellow colours with ferric oxide. Much use has been made of ferric oxide in producing glazes which are of a deep colour: practically black in moderately thick layers, though of a fine golden brown in thinner layers. These glazes are frequently described as felspathic glazes, and their composition may be given as sodium or potassium calcium aluminium silicates. To get the deep colour of these glazes, amounts of ferric oxide of the order of about 12 per cent. are required. If the percentage of ferric oxide is raised to about 15-20 per cent. some of the ferric oxide separates out on cooling and, according to the concentration of the ferric oxide, so may be seen a fine brown red colour on the surface of the glazes or bronzelike spangles of ferric oxide, or rosettes, or tree-like crystals, or even more massive crystals which to the eye look black. The Chinese made much use of this behaviour of ferric oxide. As the result of a close microscopic study of certain Chinese glazes owing their colour to ferric oxide, which undertook in collaboration with Mr. A. L. Hetherington, he was able to explain how the varied and beautiful effects seen on certain specimens of Chinese porcelain could be obtained, and to show many similar glazes produced in the laboratory to support the explanation put forward.

Ferroso-ferric oxide, magnetic oxide of iron, gives in certain glasses neutral tints of various depths, but with high concentration of this oxide a black glass can be obtained. If the concentration of the ferroso-ferric oxide be high enough, some of this oxide will come out on cooling so as to be dispersed through the glass in very minute aggregations, which are, however, presumably crystalline, since the resulting glass is appreciably magnetic. The above remarks refer to glasses containing the whole of the iron in the ferroso-ferric form. ferrous iron glass or glaze contains some ferric iron, the green colour due to the ferrous iron will be modified and various olive green tints can be obtained. There are many such coloured glazes in which the iron is principally in the ferrous state, but there is sufficient of the ferric iron present to produce the olive green tint. In a similar way small quantities of ferrous iron in a glass which contains appreciable quantities of ferric iron will

modify the yellow or brown colours due to the ferric iron and give somewhat dusky hues.

Before leaving the subject of iron I am tempted to hazard a guess at the nature of the colouring matter in lapis lazuli. In almost all the specimens which I have seen, here and there crystals of iron pyrites (ferric sulphide) can be seen. An examination of these specimens under the microscope reminds me very strongly, except for the difference of colour, of the appearances of many of the glazes very deeply coloured with ferric oxide, in which also crystals of ferric oxide can be seen. The colouring of lapis lazuli is very intense, so much so that very thin portions of it make equally thin portions of the deepest blue glass obtainable look almost white by comparison Let me for a moment direct attention to a simple experiment with solutions. If to an aqueous solution of ferric chloride, as free as possible from free hydrochloric acid, there be added quickly an aqueous solution of hydrogen sulphide, there is the production of a transient intense lapis lazuli colour. It has been suggested that this colour is due to the formation of a ferric sulphide which, in the solution, rapidly breaks down to a ferrous salt with the separation of free sulphur. My guess in respect of lapis lazuli is that the beautiful blue colour is due to minute particles of ferric sulphide, altogether too small to be seen by the microscope, dispersed through the mineral. Different concentrations of the dispersed ferric sulphide would account for the various lighter blues, full blues, and dark, almost black, blues which can be seen in specimens of lapis lazulı. I hope to be able to find a specimen of lapis lazuli of the very blackest blue colour obtainable and to examine it critically by the microscope; I also hope to be able to test the suggestion made by synthetic experiments.

In the process of making artificial ultramarine by heating together clay, sodium carbonate, sulphur, and charcoal, or some other substance rich in carbon, it has been stated, I believe, by a number of experimenters, that small amounts of iron must be present in the materials. I need scarcely mention that almost every clay contains

small, but appreciable, quantities of iron.

A few points about the third colouring agent already referred to may now be described. It is quite a common thing to see glass in windows which by long exposure to sunlight has developed colour ranging from a pink, through various depths of rose-violet almost to a marked blueviolet. Some window glasses also become coloured with a brownish-yellow tint by long exposure to sunlight, but the colour is not usually noticeable. In a glass sphere taken from a sunshine recorder, kindly lent me by Dr. G. C. Simpson, the originally colourless or slightly green glass has become a pronounced yellow-brown; the colour of this sphere is very marked in comparison with the usual colourless sphere.

The colour developed in a glass by exposure to sunlight is partly determined by the composition of the glass. Similar discoloration can also be produced in glasses by exposing them to ultra-

violet rays of shorter wave-length than those present in sunlight, to X-rays and to the radiations from radium, but the colour developed by these agencies is not, in every instance, the same as that which can be produced in the same glass by exposure to sunlight. There can be little doubt that the radiations are the cause of the colour, though what is the nature of the material which is separated out by the action of the radiations and produces the colour is not fully known. In purpled window glass, manganese has been frequently mentioned as the colouring material, it being sometimes assumed that under the influence of the radiations the colourless manganous oxide in the glass becomes oxidised to a purple manganese peroxide. In a similar way it has been suggested that the brown colour such as is seen in the sunshine sphere is to be explained by the oxidation of the ferrous iron to the ferric state. There are certain difficulties in accepting these explanations of the colours. The colourless sunshine sphere mentioned above was, a few weeks ago, a much darker vellowbrown than its companion which shows the marked brownish-yellow colour. Both spheres were colourless when new, and the present colourless one has been rendered so by heating it to a temperature All the varieties of coloured glass with which I have been able to experiment, and which owe their colour to the action of radiations, can similarly be decolorised by heating to an appropriate temperature; but of all the glasses I have tried which have been purposely coloured by ferric oxide, or by manganese dioxide, I know of no example which can be decolorised by heating, even if it is heated up to a temperature sufficiently high to re-melt it. This is not to say that these observations refute the suggestions of the nature of the colour mentioned above, but they certainly introduce difficulties which it would take too long to elaborate on this occasion.

Just as glasses can become discoloured by radiations, so have many minerals apparently been similarly affected, and in all examples which I have tried, and in which the colours were produced presumably by radiations, the colouring could be discharged by heat. Highly coloured fluorspar is a typical example; purple amethyst, smoky quartz, rose quartz, yellow quartz, and various coloured zircons, known in the gem trade as jargons, are others. All of these can be decolorised when heated to an appropriate temperature. A fine purple amethyst, for example, became clear colourless quartz at a temperature of about 400° C. A rather browner purple amethyst lost its purple at the same temperature, but had a yellow colour left, which was discharged, however, at 700° C., and the resulting quartz was white but not clear; it was opalescent.

In all the cases mentioned above it is found that when the colour of the glass or mineral is discharged by heat, the apparently colourless material shows a marked absorption in some part or other of the ultra-violet spectrum.

In the instances of glasses and fluorspar it is generally found that the decolorised specimens

exhibit marked fluorescence under the influence of ultra-violet light. I have not seen examples of crystalline quartz which show similar fluorescence, but if the decolorised amethyst be fused, the vitreous silica so obtained shows marked fluorescence Either the decolorised amethystine quartz or the same substance fused can be coloured again by exposure to radiations, the colour being developed most readily by exposure to the gammarays of radium. It is not possible, with pure crystalline quartz, which shows the highest transparency to ultra-violet radiations, to produce any coloration by submitting it to the action of the gamma-rays from radium over a period sufficient to produce marked coloration in the decolorised amethyst or in decolorised rose, yellow, or smoky quartz. Similarly, I have not found it possible with fluorspar of the highest transparency to ultra-violet light to colour it by gamma-rays, but there are many specimens of fluorspar colourless to the eve which fluoresce in the ultra-violet light, and these can be coloured by exposure to the gamma-rays from radium.

From all the observations it certainly seems that the substances I have mentioned owe their colour to the action of radiations, and become coloured only when they contain a small quantity of a suitable impurity. There is no conclusive evidence of the exact nature of the material which, separated out by the action of the radiations, imparts colour to the glass or mineral Finely dispersed metal such as calcium has been thought possible as accounting for the colouring of glass, fluorspar, and Iceland spar, but glasses which contain no calcium become coloured by radiations, and it is not impossible to imagine finely dispersed potassium or sodium as the colouring material. Silicon itself has been suggested as producing the colour of some quartz, and so has titanium, and so has carbon. It is difficult to see why silicon, which is made to go back as silica by heating, should render the quartz opaque to some ultra-violet radiations. There is no suggestion which has been made which is not open to some objection or other.

In the production of these colours, there appears to be some analogy with the ordinary changes which are observed in silver salts on exposure to light. A pure silver halide (chloride, bromide, iodide) is apparently unaffected by light. That the well-known action of light on these compounds as they are generally prepared is ascribable to the presence of small quantities of some other material or materials is generally accepted; but no one would suggest with our present knowledge that the dark material which develops in the silver salt when exposed to radiation consists of the impurity. The darkening is ascribed to decomposition of the silver salt, which decomposition is rendered possible by the presence of the impurity.

Taking into account all the observations which have been made on the effect of exposing various glasses and minerals to radiations and to cathode discharge, it would appear not unlikely that the colours produced in these experiments are ascribable to the separation from the material of one or other of its constituents by the action of the radiation, which separation is only possible provided there is present in the material a suitable impurity; but change the line of argument a little, and there are facts which would appear strongly to support the view that it is the impurity itself, in many instances, which becomes separated out in a fine state of division by the radiations and imparts the colour to the glass or mineral. We do not know. There is a mass of evidence to be considered, but much more experimental work is needed before that evidence can be dealt with and properly assessed.

## Hæmolysis.

THE discussion at the recent meeting of the British Medical Association in Edinburgh, opened by Dr Eric Ponder, afforded much information as to the nature of hæmolysis, and was particularly fruitful in clearing up the apparently contradictory data concerning the structure of the

erythrocyte or red blood corpuscle.

On one hand, it has been held that the red blood corpuscle, although to all appearance homogeneous, in reality consists of an external envelope of colourless material which forms a thin film enclosing the dissolved coloured material or hæmoglobin. Thus this envelope would be controlled by the laws of osmotic pressure. When water reaches the corpuscle it passes through the film and swells the corpuscle, causing it to become globular; eventually the envelope will burst or become sufficiently distended to allow the fluid to escape through its pores, the envelope being left. The loss of water from the cell causes shrinking and corrugation of the surface, the wrinkled or crenated form being produced. On the other hand, it has been supposed that the corpuscle is formed of a homogeneous porous material, in the pores of which the hæmoglobin is contained.

A few years ago a reversal effect was described by Brinkman, but the reaction is only apparent. After hæmolysing the cells, the solution was centrifuged and the supernatent fluid subjected to cataphoresis. This treatment resulted in the appearance of the ghosts at one pole and of the hæmoglobin at the other; on mixing the ghosts and hæmo-globin together the cells were apparently reformed, but on analysis only 50 per cent. of the hæmoglobin could be accounted for. Further, it can be shown that the isoelectric point of the normal cell and that of hæmoglobin are different, whereas the isoelectric point of the re-formed cell and hæmoglobin are the same, which is evidence that in this phenomena the cell is not re-formed as was originally thought, but that the hæmoglobin is merely adsorbed on to the surface of the ghost.

The further evidence advanced by Brinkman, that section of the red cell does not result in the exudation of fluid, is by no means contradictory to the theory of the envelope-like structure of the cell, for indeed, as Schafer pointed out, it is possible to cut a soap bubble in a similar manner, the razor

reuniting the edges of the cut membrane.

The changes in size and shape which the cell undergoes both in hypotonic solutions and in solutions containing hæmolysins afford considerable evidence that the red cell of mammals is a balloonlike structure possessed of an envelope of consider-

able strength. The work of Seifriz offers direct information. This observer has actually microdissected the human red cell, stretched its envelope, and observed the escape of fluid containing hæmoglobin from the cell. The membrane is probably similar to that suggested by Beehold, namely, that it has a protein frame-work in the interstices of which lipoids are contained. It is probably maccurate to describe the lipoids as a constituent of the cell membrane; for recent work goes to show that the lipoids are mainly if not entirely within the cell. Mellanby, in the discussion, raised the objection that the cell membrane could scarcely be of a protein and lipoid structure, as the enzymes lipase and trypsin are without hæmolytic action upon the red cell. In this instance the specificity of enzyme action must be remembered; and, further, Ponder has shown that certain proteolytic enzymes of bacterial origin are capable of

producing hæmolysis.

The ingenious method devised by Mellanby has afforded a means of making rapid and accurate observations on hæmolysis. A beam of light passes through a system of lenses, the emerging parallel rays being incident upon one of the parallel faces of the glass cell containing the suspension of corpuscles. The beam of light, after passing through the suspension, falls upon a selenium cell which is connected in circuit with a galvanometer. Variations in the intensity of light passing through the suspension of corpuscles produce variation in the deflexion of the galvanometer. The galvanometer scale is calibrated so that the readings may be made direct in terms of hæmolysis. To keep the experimental conditions constant, the parallel-faced dish is surrounded by a water bath, the temperature of which is kept constant by an electric thermo-regulator.

Using this method, Ponder has shown that a large number of lysins fall into what might be called the class of simple hæmolysins. With this class of lysins, hæmolysis results in the using up of the lysin due to its union with some protein component of the cell envelope, the reaction being of the first order. Among this simple class of hæmolysins are the majority of the hæmolytic glucosides, the soaps, salts, and acids allied to the bile salts; while recently McLachlan and Ponder have shown that the majority of the lysms of bacterial origin fall into this class. It is very interesting to note that two of these bacterial lysins, namely, that of B. histolyticus and that of Streptococcus pyogenes, are definitely known to be

proteolytic.

No. 3017, Vol. 120]

With the lysins of the saponin class, the reaction which results in hæmolysis appears to be one between the lysin and the protein of the cell envelope, and it is possible to demonstrate that these lysins will unite with other proteins to form nonhæmolytic compounds. Further, the results indicate that the combination takes place as an adsorption process. An interesting point arises with regard to the action of bile salts, as it has been shown that the serum proteins may either inhibit or accelerate the action of the bile salts according to the order in which the components of the hæmolytic system are added. The inhibitory action may be explained in the same manner as the saponin series, but the manner in which acceleration is brought about is far more difficult.

Mackie's experiments on brilliant green are of interest in this respect. 'Brilliant green' in high concentrations is a hæmolysin, but in lower concentrations it acts by 'sensitising' the cells so that the subsequent addition of small quantities of serum produce rapid lysis Further, as in the bile salt system, if the components are mixed together in the reverse order, no hæmolysis occurs. Although the sensitised cells are apparently free !

from 'brilliant green,' in reality they contain large quantities of the dye, as is evidenced by extraction with alcohol and acetone. Experiments have shown that the dye is united to the hæmoglobin as well as to the cell envelope, and that the amount taken up is nearly proportional to the amount used in bringing about the sensitivity. The reaction between the 'brilliant green' and the cells is divisible into at least two distinct changes:

(1) The adsorption of the dye by the cell en-

velope and contents.

(2) A reaction, which results in hæmolysis, occurring between the adsorbed dye and the cellenvelopes.

The amount of lysin formed will depend on the amount of dye adsorbed to the cell and the amount of protein added. If one unit of 'brilliant green' is adsorbed to the cells, this unit will unite with one unit of serum to form one unit of the new lysin. If only half a unit of protein is added, there will be insufficient protein present for the combination and one half unit of lysin will be formed. The phenomena observed with the bile salts can be shown to be identical with those observed with ' brilliant green,' the taurocholate replacing the dye as a 'sensitising agent.'

## The Leeds Meeting of the British Association

Local Arrangements.

EEDS, in these days of railway amalgamations, is supplied with railway termini in confusing profusion, the LM.S. trains arriving at no less than three different stations. All the stations are close together, however, and convenient for the reception rooms. At all stations members will be met by guides wearing armlets, and those proceeding to hostels can, if they wish, entrust their luggage to these officials for despatch to the hostels.

The inaugural meeting, where the presidential address will be delivered, is to be held in the Majestic Cinema, which lies between these main

stations, and faces on City Square.

The abundance of restaurants near the city has obviated the need for extensive provision for meals in the Reception Room, but lunch or tea can be obtained there, whilst at the University, in addition to the usual refectories, a buffet luncheon will be served in the elementary physics laboratory throughout the week.

The local handbook is now ready for distribution to members. Under the editorship of Dr. C. B. Fawcett, this handbook is more on the lines of modern regional geographic studies than has been customary. A special feature of the meeting is the series of guides to the various excursions, which are gathered into a neat cloth folder making another volume equal in size to the handbook. Under the editorship of Mr. H. E. Wroot, these excursion handbooks have been done with unusual thoroughness, and will be found of permanent

Members will also receive a guide to the extensive exhibition of scientific apparatus in the Crypt of

the Town Hall, whilst the local handbook contains brief descriptions of the special exhibits by the Air Ministry and Meteorological Office, and the British Broadcasting Corporation, which are also in the Town Hall, and of the demonstration of television, noctovision, and the phonoscope which is to be given by Mr. J. L. Baird in a room at the Education Offices next door to the Town Hall.

The General Committee, the Committee of Recommendations, and the Council will meet in the Crown Court of the Town Hall-in close proximity, therefore, to the Reception Room.

Badges are prepared for issue to members, which, by resolution of the City Council, will frank members over the Corporation tramways

during the week.

Excursions are rapidly booking up. Those to Gaping Ghyll, the St. Leger at Doncaster, Farnley Hall, and Rievaulx Abbey, and Ampleforth are already over-applied for. When possible, early applicants will receive their excursion tickets through the post before the commencement of the meeting. But in some cases their issue will, of necessity, be delayed until the meeting starts. In these cases the tickets will be awaiting members at the excursion counter in the Reception Room.

The Leeds Art Theatre announces the performance of the "Cradle Song," translated from the Spanish of G. Martini Sierra by John Garret Underhill, which will be given on the evenings of Monday, Tuesday, and Wednesday, Sept. 5-7, at

8.30 P.M.

Citizen's lectures in Leeds have been arranged as follows:

Sir Oliver Lodge. "Energy." In the Albert Hall.

Dr MacGregor Skene. "By-Products of Plant Activity." In the Philosophical Hall. Children's Lectures:

Mr. Kmgdon Ward. "Plant Hunting on the Roof of the World." In the Albert Hall.

Dr. Clarence Tierney. "Nature's Secrets," with

cinematograph illustrations. In the Majestic

Citizen's lectures have also been arranged in Pontefract, Batley, Harrogate, Huddersfield, Otley, Keighley, Wakefield, Shipley, Castleford, Guiseley, and Brighouse.

## Obituary.

SIR BRYAN DONKIN.

BY the death, on July 26, at the ripe age of B eighty-two years, of Sir Horatio Bryan Donkin, the world has lost a sane psychologist and My first meeting with a clear and rational thinker him was in the middle 'eighties, when he was dean of the Westminster Hospital, and I learned to appreciate his sterling qualities when, in my third year, I became his ward clerk. This was during what may be termed the first half of a life spent in the useful service of mankind, for he not long after forsook the practice of physic for a Government official position. As a teacher of medicine Donkin was not only clear and precise in his methods, but also possessed a broad outlook upon the duties of a physician which was in strong contrast with that of some of his colleagues on the hospital staff. To one who was mindful of the limitations imposed by medical tradition, this made work under his guidance a pleasure as well as a duty. It was my privilege in later life to realise still further the value of his friendship. The second part of his life was fully occupied by his duties as H.M. Commissioner of Prisons, duties which he took very seriously Bringing to the post his deep knowledge of medicine and his very kindly nature, he succeeded in introducing more than one salutary reform in prison organisation. He was not one to whom the prisoner was merely a bad lot', he regarded him rather as a patient, and he was, with the late Dr. Mercier, one of the pioneers of the valuable work which has been done in the psychology of crime He was medical adviser to the Prison Commission, and in 1910 delivered the Harveian oration of the Royal College of Physicians upon the subject of the inheritance of mental characters.

A well-deserved knighthood honoured Donkin's retirement at an age when many men prefer to rush out in such quiet enjoyments as, in their consideration, their remaining years permit. He, however, possessed the mind which refuses to become hide-bound with age. He knew how to keep young in mind and body, and he elected to do fighting work for what he considered to be the right. To his straightforward mental outlook and his uncompromising rationalism, everything which savoured of charlatanism and humbug, or was the result of inaccurate and loose thinking was anathema, and he never hesitated to speak and write exactly as he thought. Possessed of a ready pen, his trenchant criticisms upon such subjects as psycho-analysis and various hasty and irrational reforms were characterised by a clearness of argument that made them difficult to controvert. To young writers he was ready of help, and his kındly advice was always acceptable His loss to the cause of rationalism (he was a member of the Rationalist Press Association) is one which will be felt, and his name will be remembered by all with whom the quest of truth is a thing that MACLEOD YEARSLEY. matters.

The issue of the Physikalische Zeitschrift for June 1 contains an account of the life and work of the late Prof. F. Exner of Vienna from the pen of his pupil and colleague Prof. H. Benndorf. Franz Exner was the youngest of the five children of F. Exner, professor of philosophy at Prague, who was called to co-operate with Count Thun in the reform of Austrian education in 1848. He was born in Vienna in 1849 and lost both his parents at an early age. He was a pupil at the gymnasium at Vienna from 1860 until 1867, when he entered the University under Stefan, who although director of the physical institute had no assistants and only a miserable supply of instruments. After two years at Vienna he spent a year under Kundt at Zurich, where his brother was lecturer on Roman law. On his return to Vienna he graduated as doctor in 1871. After acting for two years as assistant to Kundt at Strasbourg, he became lecturer and assistant to von Lang at Vienna and in 1879 professor extraordinary. In 1891, on the death of Loschmidt, he became ordinary professor, and in 1907 Rector of the University. The new physical institute he designed was opened in 1913. He retired at the age limit in 1920 and died in Vienna on Nov. 15, 1926, aged seventy-seven years. During his tenure of the professorship the University of Vienna produced a large number of physicists, who now occupy most of the chairs of physics at Austrian universities and the lectureships at high schools. Of his own researches, those on atmospheric electricity are probably best known; but he also did valuable work on spectroscopy, on colour vision, and on the voltaic cell.

WE regret to announce the following deaths:

Prof. B. B. Boltwood, professor of radio-chemistry at Yale University since 1910, who did noteworthy work on radium and radio-activity, aged fifty-seven

Dr. William Burnside, F.R S., late professor of mathematics at the Royal Naval College, Greenwich,

on Aug. 21, aged seventy-five years.

Prof. E. B. Titchener, Sage professor of psychology in the Graduate School at Cornell, New York, editor for many years of the American Journal of Psychology and American editor of Mind, on Aug. 3, aged sixty years.

## News and Views.

Two esteemed veterans of science—Sir Oliver Lodge and Prof. Henry E. Armstrong-celebrate their golden weddings within a few days of one another, and on behalf of scientific workers everywhere we offer them most cordial congratulations and best wishes for further happy years. Sir Oliver and Lady Lodge were married on Aug. 22, 1877, and Prof and Mrs. Armstrong on Aug. 30, 1877. There is a distinctive quality in the personalities of the wives as well as of the partners of their triumphs and troubles for fifty years. Both Sir Oliver and Prof. Armstrong are distinguished by their originality of thought and independence of action; and both are held in affectionate regard by all who have come under their influence. Their different natures-or rather certain factors which characterise them-are represented to some extent in their eldest sons, Sir Oliver's being a life-long student of art and full of imaginative insight, while Prof. Armstrong's is devoted to industrial chemistry, and is managing director of the British Dyestuffs Corporation, Ltd Heine said that a man should be careful in the choice of his parents, and with the Lodges and Armstrongs the children have had the advantage of both wise nurture and noble nature. Well may they say, in spirit and in truth: "Let us now praise famous men, and our fathers that begat us."

ALTHOUGH young in years, the Institution of Chemical Engineers has so firmly established itself in the professions both of chemistry and of engineering as to make the appearance of a volume of its Transactions an occasion of some significance. The season has passed when a self-styled chemical engineer was merely a chemist who knew how to screw a pipe, or a young engineer who could make himself generally useful, and in particular could manipulate caustic soda with safety. Familiarity with specific industrial plant and works practice is far from being a negligible accomplishment in a chemist, but the qualifications demanded for associate-membership of the Institution go beyond this; they can best be realised by a glance at the examination papers which are reprinted in vol. 4 (1926) of the Transactions, and the examiners' report in connexion therewith. The test, the first public examination in chemical engineering held in Great Britain, was based on the requirement of a thorough general knowledge of chemical reactions and physical laws and a sound grasp of the principles of engineering; it attempted to estimate fundamental knowledge and the mental attitude brought to bear on industrial problems. The Transactions, of which Mr. S. G. M. Ure is the editor, include a report of the fourth annual corporate meeting, with Sir Frederic L. Nathan's presidential address on "Industrial Efficiency", four papers on corrosion, two on statistical methods, and one each on filtration, grinding, the saccharification of wood, alcohol motor fuels, a plant for fat extraction by solvents, a recording torsion dynamometer, refrigeration, and the laws of

air elutriation, together with reports of discussions on each of the papers.

The reader of the Transactions of the Institution of Chemical Engineers is left with a strong impression of the importance of the results both accruing and to be anticipated from the type of investigation fostered by the Institution. The chemical industries, despite, and at the same time because of, their remarkable progress, have accumulated a considerable store of problems concerning which the need for prolonged and systematic research is evident. For example, although the conversion of sawdust into alcohol (with intermediate production of sugar) has long been possible, even on a considerable scale, the process is still unsatisfactory from the point of view of its economics, both in regard to the actual saccharification and to the subsequent fermentation. The present price of petrol, although contributory, is not the only difficulty. The papers on statistical methods are, perhaps, of more than ordinary interest in times when the difference between cost and receipts is so often dangerously small. Works managers in factories other than chemical might well study the scheme of recording which is described. Although they may differ concerning the nature of the information which they require day by day in order to control and maintain production, efficiency, and economy, they may find themselves in substantial agreement as to the best means of obtaining it.

From the Second Circular of the tenth International Congress of Zoology, to be held at Budapest on Sept. 4-9 (incorrectly described in our issue of Aug. 6 as the ninth Congress), we learn that the 146 authors have already announced their intention of reading 162 papers between them. Many of these papers, while doubtless useful additions to knowledge, appear from their titles scarcely to possess that general or fundamental character which might warrant their public reading to a gathering of zoologists from all parts of the civilised world. The subject of general interest that has attracted a large number is tissue-culture, and communications dealing with it are promised by Carrel of New York; Centanni of Modena; Demuth and van Riesen, A. Fischer, Kımura, and Laser of Berlin; Gassul of Kazan; Haan of Groningen, Harrison of New Haven; Krontowsky of Kiev; Küster of Giessen; Levi and Olivo of Turin; Timofejewsky of Tomsk, and Zweibaum of Warsaw. Tissue-culture may perhaps pass, but when one finds several titles like "Zur Physiologie der Tumorzellen" and "Immunity in relation to Implanted Malignant Tumours," or others on white blood corpuscles, one begins to inquire what is meant by 'zoology.' Fortunately the old-fashioned zoologist will find a few papers of broad interest, such as Racovitza "Espèce et lignée," Van Bemmelen "Organismen-Begriff und Zellenlehre," Fedotov "On the Relations between the Classes of Echinoderma," and L. O. Howard "On the International Aspects of Entomology." Or if his tastes are more sporting, he may hear the unweamed Stiles stand up to the irrepressible Poche on the rules of nomenclature.

THE part of the chain of Mont Blanc recently christened "Monte Mussolini" is one of the many peaks comprised in the massif dominated by and generally known as Mont Blanc, but it is wholly in Italian territory. There are at least fifteen high peaks in the chain, from Mont Joli, 2670 metres high, to the Aiguille du Tour, 3542 metres, the highest peak, Mont Blanc, being 4810 metres. Monte Rosa, its Italian sister, rises to 4683 metres, while the highest summit in the Pyrenees, the Nethou, attains only to 3404 metres. The Franco-Italian frontier runs (in theory) along the summits of the high peaks of Mont Blanc, but in one place the Italian line lies on the wrong side. It happened that when Savoy was ceded to France, in 1860, Victor Emanuel expressly reserved a little enclave on the other side, as that spot was the haunt of the chamois he so dearly loved to hunt. It was in a somewhat similar way that the ex-Emperor of Germany, when the frontier was delineated between British, and German East Africa, persuaded the British Government to deflect the otherwise straight line so as to include Kilimanjaro, as he wished Germany to possess the highest mountain in Africa.

An account of the work of the Discovery Expedition up till Aug. 18, 1926, has already appeared in these pages (NATURE, Oct. 20, 1926, p. 628). In the recently published first annual Report of the expedition (London: H.M. Stationery Office. 1s. 6d. net) an outline of the work carried out for the remainder of that year is given. The R.R S. Discovery, together with the additional Research Steam Ship William Scoresby, which arrived at Cape Town on Aug. 1. embarked on the programme originally arranged. Leaving Simon's Town on Sept. 21, the Discovery proceeded on two short cruises off the African coast for work off the Saldanha Bay whaling grounds. On Oct. 27 she left Africa for South Georgia, arriving there on Dec. 5, after having to change the route originally chosen-south from the Cape to about Lat. 58°—owing to exceptional ice conditions. Meanwhile the William Scoresby had been employed in whale marking and taking plankton collections off the African coast until Oct. 21, after which she sailed for South Georgia. Arriving before the Discovery, on Nov. 8, a line of plankton stations was run by her along the north-west coast, and whale hunting was undertaken for marking purposes. Afterwards the two ships combined in a plankton survey of the whaling grounds. Observations were resumed by the staff of the Marine Station at Grytviken, in South Georgia, early in November. Amongst other valuable data obtained by them during their previous stay at Saldanha Bay was an embryo of a Sei whale, only 2-3 mm. long, believed to be the youngest embryo which has ever been found in a whale. The Discovery left Simon's Town for Portsmouth on July 18 via the west coast of Africa and is expected to arrive in October. Before

further sea work is undertaken, the scientific staff will spend two or three months working up the results of their collections, which are housed in the Natural History Museum.

THE reports of the electrical engineers of the Brighton and Bradford Corporations who have independently visited the United States to inspect American power stations and transmission lines are of interest. Abstracts of them have been published recently in various technical journals. In their opinion, the Americans are in advance of Great Britain in boiler-house practice. The use of pulverused fuel is becoming common. In New York the Steam Corporation supplies its consumers directly with 5000 million pounds of steam every year for heating purposes. The high-pressure steam pipes, covered with heat-resisting material and provided with valves and expansion joints, have been admirably designed. If we except the large size of the steam turbines, there was little in the power stations themselves that was found to be novel. Many of the new capital stations have very much higher load factors than any in Great Britain, being loaded in some cases up to 80 per cent. of their maximum capacity. The price of electricity, however, is not cheap. In the opinion of these British engineers the overhead transmission lines, worked at very high pressures which convey large supplies of power from one station to another, instead of marring the beauty of the landscape, give an added interest to it. In Chicago the Commonwealth Edison Company has constructed a very large new generating station. There is an underground ring main which will be operated at 132,000 volts and will inter-connect all the power plants and substations of the company. This is a new departure, and its operation will be studied with great interest by electricians. The sign lighting in Broadway and Times Square, New York, is marvellous, and greatly improves the somewhat meagre direct lighting from street lamps. Some of the smaller cities and towns visited had better street lighting than New York. We agree with the statement that it would be a great boon to all road users in Brighton if the candle power of all the street lamps was doubled.

THE rapid improvement which is taking place in the thermal efficiency of electric generating stations is very satisfactory, as it shows that old-fashioned apparatus is being scrapped. In the July number of World Power, H. Quigley gives statistics which indicate some of the economies which have been effected by this increased efficiency. During the last five years the average fuel consumption per electric unit generated in British generating stations has diminished from 3.11 lb. to 2.40 lb. If this diminution had not taken place, about two and a half million tons of coal in addition would have been consumed. The average of 2.4 lb. per unit is not much greater than the average of 2.1 lb. per unit obtained in America. The author, taking the average of the twenty-five largest and most efficient stations in Great Britain, finds that since 1922 the average consumption per unit generated has fallen from 2 05 lb. to 1.80 lb. Twenty-five per cent. of the national output of electricity is generated by these stations. The Barton station at Manchester achieved in 1925-26 the record efficiency, generating a unit for every 1 36 lb. of coal consumed. Practically all the modern generating plant in these stations has been manufactured by British firms. Provided that trade is prosperous, so that the load factor of the generating stations continues to increase, there is every prospect of much better results being attained in the immediate future. The new Government schemes will help in this direction

The first issue has appeared of the Journal of the Ministry of Agriculture for Northern Ireland (Belfast H.M. Stationery Office, price 2s. 6d), its object being to provide a medium for the publication of the results obtained by the different agricultural research divisions of Northern Ireland. The articles are intended to be in a form which should render them easily understood by the farmer, while in no way affecting their scientific value. One of the chief problems is to discover a phosphatic fertiliser which will be suitable to the crops and soils of the district, and also an efficient substitute for the high grade basic slag now rapidly disappearing from the market. Experiments are recorded which show that North African rock phosphates can be successfully used, with the further advantage of reduction in cost Investigations in connexion with the loss of vigour in stocks of potatoes are of special importance in view of the efforts being made to develop a seed potato trade in Northern Ireland. Deterioration is much more rapid in early than late districts, thus enabling the latter to provide healthy stocks for the former when change of seed is needed. The practice of cutting potatoes is quite successful on light, dry soils, provided it is done at the time of planting. With regard to plant diseases. American gooseberry mildew is one of the most serious problems confronting the fruit growers in Ireland, but it can be successfully controlled by suitable spray mixtures. Silage investigations are of particular importance owing to the prominent part played by live stock in the farming of this district. The yield from a mixture of oats, beans, vetches, and peas, though less than the average yield of turnips, is more certain, and further, the crop has a considerably higher dry matter and feeding value than roots. In addition to the main articles. bibliographical reviews and short notices of recent important agricultural publications are appended, which should prove of the greatest value to both farmer and agricultural instructor.

In 1928, on Sept. 24-Oct 6, it is proposed to hold a Fuel Conference at the Imperial Institute, London. This will be a sectional meeting under the auspices of the International Council for the Organisation of World Power Conferences—the first of which was held at Wembley in 1924. Lord Balfour has accepted the honorary presidentship, and Sir Alfred Mond the presidentship, while the chief participating industries,

including coal, oil, gas, and chemicals, are strongly represented in the organising committees technical programme covers solid, liquid, and gaseous fuels, utilisation of fuel, and the general aspects of the fuel question, including training. The programme will include questions of composition and classification of fuel, preparation, storage, handling, and transmission. Evidently the scope of the conference is extremely wide. To shorten proceedings, it is proposed to accept normally only authoritative reports from representative bodies of the participating countries. A preliminary announcement has been issued from the central office, 36 Kingsway, London. W C 2. The secretariat consists of Messrs. Sholto S. Ogilvie and M W Burt (general secretaries) and Dr E. W. Smith and E. J. Fottrell (joint technical secretailes)

The chief interest of the annual report for 1925 -1926 of Bergens Museum (Bergens Museum Aaresberetning, 1925-1926) drawn up by the Director, Prof. Carl Frederic Kolderup, lies in the large amount of original research forthcoming from all departments, which shows a very flourishing state of aftairs. Amongst the many well-known and valuable publications of the Museum is included Vol. 9, parts 11 and 12, of the late G. O. Sars's "An Account of the Crustacea of Norway," continuing the Ostracoda. Attached to the Museum is the Biological Station at Herdla, and here many visitors have availed themselves of the opportunities offered to workers, where the Director, Prof. Aug. Brinkmann, and his assistants are themselves engaged in investigating marine problems. At the Geophysics Institute hydrographical work under the direction of Prof. Helland-Hansen is being carried out, observations being undertaken on temperature, salinity, and carbon dioxide content of the fjords round Bergen, with direct registry of the density of the upper water layers by means of the 'pycnosonde,' an apparatus recently constructed by Dr. D. la Cour, Director of the Danish Meteorological Institute.

Although historically unimportant, Tut-ankhamon will no doubt long continue to occupy a prominent place in popular regard and an added interest be taken in any historical details concerning him or his entourage which can be brought to light. Prof. Forrer has now published in full a corrected and amended copy of the Hittite cuneiform texts relating to the negotiations between Tut-ankh-amon's widow and the Hittite king Subbiluliumas for her remarriage, which has been translated by Prof. Sayce in Ancient Egypt for June. While the king was at Carchemish, the queen sent him an envoy asking for one of his sons in marriage as "My husband is dead and I have no son." With characteristic caution the king sent the Chief Secretary, his High Chamberlain, to Egypt "to bring back an accurate report as to whether she is in any way deceiving me and what has become of the son of their (late) master," a proceeding which seems to have aroused the queen to some indignation, which she expresses in a subsequent despatch. This text raises an interesting question as to the method of making and filing these official records. Apparently there were two copies, one on clay and one on bronze, one of which was a draft, though which is not quite clear. Sir Flinders Petrie adds a figure of the Princess from the tomb of Panehesy at Tell el Amarna

THE need for scientific research in the fishing industries is concisely stated by Maurice Holland in a short paper which has been issued by the U.S National Research Council (No. 74, Reprint and Circular Series of the National Research Council, Dec. 1926). His remarks indicate the indifference with which the fisheries have, in the past, supported a rational research programme. Whilst dealing only with the specific problems presented by the United States, his remarks are generally applicable Fisheries products, in spite of their importance, make up no more than 3 per cent. of the world's food supply, this only represents 40 per cent. of the total catch, and the remainder gives but a small return. The author gives a summary of future commercial possibilities in which the 60 per cent. by-products might be profitably utilised. A comparison is made with other industries, particularly with the meat-packing industry; it appears that out of 115 industries, less than ten have a higher number of wage earners. though the value of the annual product per person is very low. It is suggested that the formation of a fisheries bureau similar in scope to the Conseil Permanent International of Atlantic countries, but dealing particularly with the Pacific countries, would be of great help in future developments.

Under the title of "Flottierende Stationen," Dr. H. C. Redeke, in "Abderhalden's Handbuch der biologischen Arbeitsmethoden" (Abt. 9, Teil 2/2, pp. 1249-1257, 1927), gives particulars of a houseboat used for inland fishery research on the Dutch waterways. This well-equipped laboratory, built on a barge 81 ft. × 19 ft., is illustrated by a photograph, where it is seen moored in a placid Dutch waterway—an ideal laboratory and summer residence which can be towed from place to place at small expense as occasion demands. The relative advantages of wood over iron construction, equipment, and accommodation are discussed. Three other floating biological laboratories exist, on Lough Derg, in Illinois, and in Quebec.

In a note entitled "Non-Marine Mollusca of the Belgian Congo" in our issue of Aug 6, p. 204, reference was made to the lack of an index to the collections. A correspondent informs us that, in answer to an inquiry, the Librarian of the American Museum of Natural History stated that an index to "The Aquatic Mullusks . . ." will be ready very shortly.

THE April issue of the Proceedings of the Imperial Academy of Japan contains a list of the grants to be made out of the research funds of the Academy for the fiscal year 1927-28. Of the seventy-one grants made, eighteen are for religious, historical, literary,

No. 3017, Vol. 120]

The state of the s

and economic studies, and fifty-three for scientific and medical work. In the latter group may be mentioned investigations on asteroids, earthquakes, Japanese coal and petroleum, air movements, synthesis of paraffins, soil and its organisms, crops, genetics of insects, nutriments, effects of poisons on the nervous system, metabolism, and cancer. Further grants recommended by the Academy were made out of the Toshogu Memorial Fund by the Board of Directors of that Fund

The British Museum (Natural History) has recently issued a "Guide to the Crustacea," by Dr. W. T. Calman, which forms an excellent handbook to the study of the specimens of the class Crustacea exhibited in the galleries of the Museum. Brief accounts are added of the Trilobita and the Pycnogonida. The guide is well illustrated by fifty-three drawings and photographs.

A CATALOGUE (No. 499) of second-hand books—some 341 in number—on British and foreign birds has just been issued by Mr F Edwards, 83A High Street, Marylebone, W 1. It can be had from the bookseller upon application.

A CATALOGUE (No. 1, New Series) of second-hand books, pamphlets, and serials relating to natural history has reached us from Mr. A. J. Bateman, "Tintern," Hampden Park, Eastbourne. Some 850 works are listed. The prices asked appear to be reasonable.

MESSRS. W. Heffer and Sons, Ltd., 4 Petty Cury, Cambridge, announce for early publication a new book by Dr H Martin Leake, entitled "Land Tenure and Agricultural Production in the Tropics," being a discussion on the influence of the land policy on development in tropical countries.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned .-- A lecturer in physics and electrical engineering at the Leigh Municipal College—The Director of Education, Town Hall, Leigh, Lancs. (Sept. 3). An assistant in the Records Bureau of the Department of Scientific and Industrial Research—The Secretary, Department of Scientific and Industrial Research, 16 Old Queen Street, S.W.1 (Sept. 12). A specialist in medical entomology in the Ankylostoma and Bılharsia Research Section of the Public Health Laboratories of the Egyptian Government—The Under-Secretary of State, Department of Public Health, Cairo, Egypt (Sept. 15particulars from the Egyptian Legation, 75 South Audley Street, W.1). An assistant bacteriologist in the East African Medical Service-The Private Secretary (Appointments), Colonial Office (38 Old Queen Street, S.W 1 (Sept. 17). A lecturer in engineering at the Cape Technical College, Cape Town-Chalmers and Guthrie, Ltd., 9 Idol Lane, E.C.3 (Sept. 19). An assistant lecturer in electrical engineering at the Manchester Municipal College of

Technology—The Registrar, Municipal College of Technology, Manchester (Sept. 19). A demonstrator in agricultural botany in the University of Reading—The Registrar, The University, Reading (Sept 24). A senior lecturer in physiology in the University of the Witwatersrand, Johannesburg—The Secretary. Office of the High Commissioner for the Union of South Africa, Trafalgar Square. W C.2 (Sept. 26). Research appointments, as follow, under the Ministry of Agriculture, Cairo, Egypt—a chief entomologist, an entomologist for entomologisal research, a mycologist, and another entomologist, each in the Plant Protection Section; two botanists in the Botanical Section; and a chief chemist, a soil physicist, and a soil bacteriologist in the Chemical Section—The

Under-Secretary of State, Ministry of Agriculture, Cairo, Egypt (Oct. 1). A director of tobacco investigations under the Commonwealth Government and the States of Australia—The Official Secretary, Commonwealth of Australia, Australia House, Strand, W.C.2 (Oct. 17). A physics specialist at the Liverpool Collegiate School—The Director of Education, 14 Sir Thomas Street, Liverpool. A lecturer in estate management (including farm machinery) at the Harper Adams Agricultural College—The Principal, Harper Adams Agricultural College, Newport, Shropshire. A chemical laboratory assistant in the experimental department of the Fine Cotton Spinners' and Doublers' Association, Ltd.—The Chief of the Department, Rock Bank, Bollington, Macclesfield.

#### Our Astronomical Column.

NAKED-EYE SUNSPOT —A recent spot of considerable size is the eighth to be observed this year as a naked-eye object on the sun's disc. The growth of the spot was rapid, and it originated in a place immediately in front of the disappearing fragments of a group which was near the east limb on Aug 9. The following table shows the rate of growth, the area being measured in the customary units of millionths of the sun's hemisphere:

 Date
 . . Aug. 12
 Aug 13
 Aug 14
 Aug 15
 Aug 16
 Aug 17

 Area
 . . . 25
 160
 550
 900
 1150
 1300

 Lone from central meridian
 25°E
 12°E
 2°W
 15°W
 28°W
 41°W

On Aug. 16 the spot was approximately 40,000 miles in length and 30,000 miles broad. Its structure was complex with several umbræ. In appearance it resembled those spots the magnetic polarities of which are found to be irregular and are, according to the Mt. Wilson observers, most likely to be associated with terrestrial magnetic disturbances. In the present instance no disturbance has been reported, but as the spot, when near the central meridian, had not reached its maximum growth, it will be of interest to await its second transit about Scpt. 10. The duration of large irregular spots is not proportionate to their size, a smaller spot of regular outline often lasting much longer, but the return of the recent spot may well be expected on Sept. 4 at position angle 122° from the north point on the sun's east limb. Other details of the spot are as follows:

No. Date on Disc Central Meridian Latitude. Max Area

8 Aug. 11-20 Aug 14-2 10° S 1/750 of hemisphere.

The Temperature of Mars.—Prof. H N. Russell gives in The Scientific American for July a simple description of the work of Drs. Coblentz and Lampland on the heat received from Mars (see also Nature, Sept. 19, 1925, p. 439). They used a very delicate thermocouple, and screens of glass, quartz, fluorspar, or cells containing water to isolate different wave-lengths of the heat spectrum. The chief difficulties were the effects of the atmospheres of the two planets, that of the terrestrial atmosphere was minimised by the high altitude and dry climate of Flagstaff. It is noted that a moist, slightly hazy atmosphere tends to increase the surface temperature of a planet since it retards the escape of radiation of long wave-length: but for this very reason observations made from another planet are

likely to give too low a value for the surface temperature, since they are derived largely from reflection from the upper surface of the haze. It is thus explained why the temperature at the melting edge of the polar cap was measured as  $-75^{\circ}$  F. in 1924, when it must have been in the neighbourhood of  $30^{\circ}$  F.

Taking the necessary corrections into consideration, Dr Coblentz gives the following estimates of the noon temperatures of different zones of Mars in the late summer of the southern hemisphere:

Zone,		Temperature (F)				
South polar region				$15^{\circ}$	to	50°
South temperate zone				65	,,	75
Tropics				65	,,	85
North temperate zone				30	,,	60
North polar region (sou	ather	n part)		- 40	•••	+10

The nights are probably very cold, even at the equator.

The above values are stated to be in good agreement with those found by Messrs. Pettit and Nicholson at Mt. Wilson in 1924. For example, they gave the noon temperature in the tropics as 80°, after correcting for the effects of cloud and haze.

The temperatures as a whole are much higher than was previously thought probable, and this is obviously a point in favour of the planet's habitability.

The Mass of Venus.—The issue for June of Mon. Not. R.A.S. contains two papers on this subject Dr. H. Spencer Jones rediscusses the observations of Mars made with the Cape heliometer at each opposition from 1899 to 1924, applying some necessary corrections to a former discussion. His new value for the mass of Venus in terms of the sun is 1/411.300, with a probable error of 1 part in 300. This is 1 per cent. smaller than Newcomb's mass and 3 per cent. smaller than Le Verrier's.

The other paper, by Dr. J. K. Fotheringham, deals with all determinations of the mass of Venus from 1750 to the present time, and shows that they may be divided into three groups. The observations from 1750 to 1846 give a small mass, those from 1846 to 1888 a large one, the remainder an intermediate value, nearer the first than the second. Dr. Fotheringham regards the change in the mass as real, but most people will consider this as improbable as that the length of the seconds pendulum should change by an inch or so. It is, however, very useful to have all this material rediscussed, though the apparent change remains a puzzle.

## Research Items.

AINU NEOLITHIC IMPLEMENTS.—We have received a communication from Dr. N. Gordon Munro of Karunzawa, Japan, in reference to our comments on the Rev. F. Smith's book, "Prehistoric Man and the Cambridge Gravels" (see Nature, April 9, p. 523), and directing attention to the question of the derivation of certain types of paleolithic implements from shell forms Dr. Munro states that among his collection of Amu neolithic implements, now unfortunately de-troyed by the earthquake, were a considerable number commonly called Tengu no meshi kan, or ricespoons of the Tengu, Tengu possibly meaning spirits of the wild or soil. Inspection suggested that these were copies of shells, and as they were made of igneous rock, obsidian, or chert, rarely agate, there could be no question of the conchoidal fracture being responsible for the form. Conventionalism had resulted in a notched or button-shaped survival of the umbo, but of the attempted representation of the convexity and concavity of the shell there could be no doubt. Kai stands for both spoon and shell, and in the ancient Chinese pictographs the spoon is represented by a shell, and shells are still in use in Japan as spoons. This may be in part responsible for the survival of the name quoted. Dr. Munro has exammed a large number of specimens from the Thames gravels, and among them has recognised many as sımılar to his Ainu specimens,—a resemblance based upon the ensemble rather than the conchoidal fracture. He suggests that the palæolithic artisan noted the resemblance and was influenced thereby to transfer the functional form of the shell to the fimt.

Consanguineous Marriage in Ancient Egypt. —In Ancient Egypt for June, Miss M. A Murray examines a number of genealogies recorded on stela of the Middle Kingdom with the view of extracting the relationships of those who are mentioned as married or whose marriage can be inferred Consangumeous marriages occur, though infrequently; but occasionally the names suggest that the custom had been more general. Such a name, for example, as "My mother is my sister" indicates a father-daughter marriage and "My father is my brother" a mother-son union. Particularity of definition is such in some cases as to preclude the argument against these types of marriage that terms of relationship were then used more loosely and must not be construed literally. It is to be noted that these marriages occur in all classes of society, and there are those of small officials not necessarily connected with the royal house or the families of great nobles. It is, no doubt, also significant that these marriages are usually found in families where the name Wah-ka, Bebu, or Beby, and names compounded with Khnum and Sebek are used. In the genealogy of Wah-ka is a father-daughter marriage, his grandfather having married his two daughters, one of whom was Wah-ka's mother. Another father-daughter marriage and an aunt-nephew marriage is shown in the stele of Horzeruy. A mother-son union is probable in the case of Nefer-rud, whose mother and wife Hetept were possibly one and the same. The genealogy of Sen-mry Kheper-ka-ra can be explained only as the marriage of one man with three women, two of whom were his own daughters. Mother-son marriages occur also on the stelæ of Sebek-dedu, the scribe of the stone-masons, Pa-unt, and the goldsmith, Sebek-hetep. The marriage of Se-hetep-ib shows the union of brother and sister, while an aunt-nephew union of the kind familiar from the parentage of Moses occurs in the genealogy of Ptah-sankh-en.

Puja —In the Indian Antiquary for May and July is a study in two instalments of certain elements in Hinduism by Prof Jarl Charpentier of Upsala. The religion of the Aryans, as set forth in the Rig-Veda, was the religion of the upper classes, it was too complicated and its ritual too expensive for the masses All its gods were males and there were no temples and no images. Among the aboriginal subject races the religion of the Munda-speaking tribes was a crude form of animism including human sacrifice to an earth goddess; while the Dravidian religion included the worship of she-devils and the spirits of the dead, the female element was predominant and crude idols were put up either in the open air or under the shelter of small temples. Sacrifices were characterised by the use of blood which was smeared on the idol or the worshippers and was used when poured on cooked rice as a common meal These forms of religion were totally opposed to that of the Arvans, which, however, at an early date compromised by incorporating godlings and taking in idols and temples. These gods and godlings are now adored by a number of ceremonies comprised under the name puja, which takes a central place in the daily routine followed in Hindu temples, in which the god is treated as a living monarch routine the characteristic element is the washing of the idol or the sprinkling of the linga with water or with honey, curds, honeyed water, etc., or the sinearing of it with certain ointments, powders, or oily substances which are generally of a brilliant red or yellow colour. Of the various derivations, few in number, offered for the term puja, the most likely seems the Dravidian root pûçu, Kanarese pûsu, meaning to sinear, put on sticky substances, to daub, to paint. Now in all the more primitive cults of India the most common way of adoring the various gods is to smear the wooden logs, uncarved stones or idols representing them with oil or lac, cinnabar, turmeric, or other red or yellow dyestuffs; and this practice is even extended to the tools of certain castes at various seasons, eg, the Rajput guns, the Thug pick-axe, the agricultural implements of the Decean. The rite thus has its origin in very primitive conditions as it is practised among low-caste peoples, and in advanced Hinduism it is now most frequent in the case of such gods as Ganesa and Hanuman who are of low origin.

The Feeding Mechanism of Nebalia.—Prof. H. G. Cannon (Trans. R. Soc. Edin., 55, No. 15, 1927) describes the feeding mechanism of Nebalia bipes—a mud-dwelling form which feeds on particles filtered from a food stream produced by its foliaceous trunk limbs. The food stream enters at the anterior end and makes its exit at the posterior end of the carapace. The current is produced by the oscillatory movements of the trunk limbs, and a detailed account is given of the movements and of the setal armature of these appendages. The mouth parts, structurally and in their method of functioning, closely resemble those of a mysid. From a comparison with Paranebalia it is suggested that Nebalia evolved from a mysid, or from some other primitive malacostracan possessing a feeding mechanism similar to that of Hemimysis, that took to living in mud. The foliaceous limbs are in no way primitive, but have evolved from typical biramous malacostracan limbs in connexion with the new method of filter feeding.

EEL LARVE.—In a recent issue (vol. 2, No. 1, p. 38) of the Journal du Conseil Permanent Inter-

national pour l'Exploration de la Mer, Prof. Johs. Schmidt supplies a new record of the capture of the larvæ of the common eel in the Faroe-Shetland Channel Previous to 1926, only four specimens of metamorphosing eel larvæ not vet at the elver stage had been taken east of Long. 5° W., but on Aug. 11, 1926, the Dana, under the supervision of Å. V. Taning, made a capture of 297 larvæ in the southern part of the Faroe-Shetland Channel—60° 35′ N., 3° 45′ W.—over soundings of 366 and 470 metres. The great majority were in the metamorphosis Stages II and III, although 9 per cent were in Stage I and had not commenced metamorphosis Most of the larvæ were found at a depth of 20-30 metres below the surface. The average lengths for the various stages in the retrograde metamorphosis were, Stage III, 75 46 mm., Stage II, 74 33 mm., and Stage IV (of which there were only 11 specimens), 72 46 mm.

GRASSES OF THE CENTRAL ANDES -The Smithsonian Institution has just issued a work on the grasses of the Central Andes—Ecuador, Peru, and Bolivia, by that eminent agrostologist, Dr A S Hitchcock (Con. U.S. Nat. Herb., vol. 24, part 8). Most of the region is mountainous, and although lying under the equator, many ranges and peaks are capped with snow. The flora is mainly temperate and alpine, but becomes tropical on the coastal plain and on the eastern slope There are wide variations in rainfall over the region, and because of the extremes of altitude and precipitation the giass flora is large and varied. While the very detailed information in the book has been collated from many herbaria, and every available source of information has been laid under contribution, the list of grasses is based primarily upon the specimens in the United States National Herbarum. The descriptive lists and keys include 124 genera and 605 species, of which 29 species are new.

GROWTH OF POLLEN TUBES -P. O'Conner, experimenting on the growth of pollen grains, finds that malic acid has no directive influence on the growth of pollen tubes of Angiosperms (Scientific Proceedings, Royal Dublin Society, vol. 18 (N.S.). No. 40, July 1927) By adding watery extract of stigmas to a medium consisting of gelatine and cane sugar, he was able to inhibit growth of all pollen except that of species from which extract was made. medium containing extract of tulip stigmas which had been inseminated with a mixture of crocus, daffodil, and wallflower pollen, permitted the development of the tulip pollen tubes only. As the hydrogen ion concentrations of the various stigma extracts were of much the same order, he rules out the possibility of acidity as a determining factor. Osmotic concentration is similarly eliminated. The inhibiting substances are diffusible through permeable membranes and are not destroyed by boiling, which tends rather to accentuate their inhibitory effects, probably through a reduction of oxygen tension Where growth of pollen tubes did occur in an inhibiting medium, the tubes produced were frequently of a monstrous type On "general biological considerations" the inhibiting substances are supposed to be of an amino compound nature. Extracts from other parts of the plant were found equally inhibitive of the growth of foreign pollen grains, and the author suggests a specificity of the sap, and considers that possibly the 'sap' may be the source of mutation, and the protoplasm largely its instrument.

SIZE OF THE GENE.—The conceptions connected with dominant and recessive genes are closely analysed by Dr. A. S. Serebrovsky (*Jour. Genetics*, vol. 18,

No. 2) in a paper on the influence of the 'purple' gene on crossing over in the middle part of chromosome II. in Drosophila. The experiments were carried out in a thermostat owing to the well-known effect of temperature on crossing-over, and 120,000 flies were bred and examined in three months. Since the age of the female also affects the crossing-over, the eggs laid during the first and second six-day periods of life were kept separate. The records of females which hatch on successive days were also kept separate, as the later emerging flies become progressively smaller until the last are dwarfs. Flies which hatched late showed diminished crossing-over, although this was not very regular. A new method is worked out for determining the approximate size of the 'purple' gene from the data of crossing-over. It is suggested that genes may vary in size, and that the presence absence theory may be revived if divisibility of the genes is admitted. There is a certain periodicity in the occurrence of cross-overs, but the coefficient of variation in their frequency is of the same order as other biological co-efficients of variation.

CARBON RATIO THEORY —In the Journal of the Institute of Petroleum Technologists for April, Dr. Murray Stuart raises a significant point in connexion with the real interpretation of the carbon-ratio theory As is generally known, David White first observed the relationship between the carbon-ratio of coals and the likelihood of oil occurrence in associated strata in America, since which time the theory has been applied to similar occurrences in many parts of the world, perhaps with indifferent success. However, it is now pointed out that what has hitherto been loosely referred to as the carbon ratio, i.e. ratio of C to H, is really not a ratio at all, since what is meant is the percentage of fixed carbon (pure coal basis) in the coal. The analysis of coal is usually expressed in terms of moisture, fixed carbon, volatile matter. and ash; neglecting moisture and ash, it is the relationship between fixed carbon and volatile matter which constitutes the so-called carbon ratio. "As the percentage ratio is taken as the basis of the carbon-ratio theory, it is not necessary to express the ratio as a ratio, . . . (but as) the percentage of fixed carbon in the sum total of the fixed carbon plus volatile matter of coal." Thus if the carbon ratio is quoted as 55, then the ratio of fixed carbon to volatile matter in the coal is 45 To some extent the mistake has arisen in thinking that all the carbon in coal exists in the fixed carbon portion and that the volatile matter is exclusively hydrogen, in which case the C'H ratio is a reasonable interpretation; but, as Dr. Murray Stuart points out, there is a considerable quantity of carbon in the volatile matter of a coal, and coals are known where the carbon ratio is 50, but where the percentage ratio of carbon to hydrogen is more than 90, in the same examples.

Cat Creek and Devil's Basin Oilfields, Montana.—In a somewhat unusually stereotyped bulletin (No. 786B) of the United States Geological Survey, Mr. Frank Reeves gives an account of two recently discovered oilfields in Montana. The area falls within the Great Plains province, though it possesses a diversified topography, much of which is formed by the Lance formation (? Eocene). The principal structural feature is that of the Cat Creek-Devil's Basin uplift, a rectangular area of some 2000 square miles, characterised by numerous and pronounced domes along the margins. Of the two oilfields in the region, that of Cat Creek is commercially the more important, having a daily production of about 2800 barrels (1926) from 190 wells. Four distinct sands have been recognised in the field, the

Mosby, First, Second, and Third sands, most of the oil being derived from the First and Second horizons, especially the former, the stratigraphical horizon of which is the base of the Colorado Shale, bottom of the Upper Cretaceous. Mr. Reeves believes that the source of the oil is the Colorado Shale, which, besides having the colour suggestive of abundant organic matter, has been proved by testing to contain free oil and pyrobitumens; this formation is, incidentally, the most prolific oil-producing horizon in the Rocky Mountain region. The Cat Creek oil is of mixed base, with a gravity varying from 47° to 50° Baumé and containing little sulphur; thus it is a remarkably light oil, some 6° lighter than the average Appalachian The author does not believe that such oil is due to natural fractionation of heavy oil through porous strata of the fuller's earth type, as suggested in some quarters, but attributes its high quality to normal conditions, pointing out that only a slight modification of much of the Cretaceous oil of this region is necessary to produce a crude of the type met with at Cat Creek.

THE SPECTRA OF ZIRCONIUM AND SCANDIUM.-Papers 548 and 549 of the United States Bureau of Standards are devoted to wave-length measurements in the arc and spark spectra of zirconium, and in the arc spectrum of scandium, by C. C Kiess and W. F. The scandium ammonium Meggers respectively. oxalate which was used was originally prepared and purified by Auer von Welsbach, and had at one time formed part of Prof. Eder's collection. The zirconium metal, although of high chemical purity, showed considerable spectroscopic contamination, and amongst the foreign lines there were a number due to the recently discovered element hafnium. 700 scandium lines are listed between 2500 Å.U. and 8600 Å.U., and about 1500 zirconium lines between 2100 Å.U. and 9300 Å.U. Both arc spectra are superposed on a system of bands. The latter have not been analysed, but it is stated that a very satisfactory analysis of the line spectra of scandium has been effected, which will be published shortly.

ELECTROMETER CAPACITANCES.—In the issue of the Physikalische Zeitschrift for June 15, Dr. H. Witte gives an account of his measurements of the capacitances of a number of electrometers and their variation with the deflexion of the instrument The work was undertaken at the suggestion of Prof. Ludewig and was supported by a grant from the Helmholtz Asso-Two radio valve circuits of frequency 105 were magnetically coupled by a circuit containing a telephone to a third similar valve circuit. Two of the valve circuits contained small adjustable capacitances. and the method of measurement consisted in inserting the electrometer in one valve circuit and either counting the number of beats heard in the telephone or in adjusting one of the capacitances until the beats ceased. For a single filament electrometer with attracting plates, the positions of the plates made a change of 4 per cent. in the capacitance, which was of the order 1.5 cm. For a Wulf single filament electrometer without attracting plates, the deflexion of the filament altered the capacitance of 2·1 cm. by about 2 per cent. For a gold-leaf electroscope of the Elster and Geitel type, the capacitance, 8 cm., varied 6 per cent. with the deflexion.

LIMITING VOLUMES AND CRITICAL ISOTHERMALS OF LIQUIDS.—Although in most of the equations of state hitherto proposed the limiting volume of a liquid at infinitely high pressure,  $v_{\infty}$ , has been assumed constant and equal to the limiting volume at the absolute zero of temperature,  $v_0$ , this assumption does not seem to have any theoretical basis. The *Proceedings of the* 

Physico-Mathematical Society of Japan for Feb. 1927 contain a paper by Y. Tasiro in which values for  $v_{\infty}$  for some organic liquids have been extrapolated from Bridgman's well-known data. The calculated values of  $v_{\infty}$  tend to increase as temperature decreases, but since the method of extrapolation is of doubtful accuracy, it is not safe to draw any positive conclusions as to the constancy of  $v_{\infty}$ . On comparison with the corresponding calculated values of  $v_0$ , however, it is quite clear that the two quantities are not equal,  $v_{\infty}$  being much smaller than  $v_0$ . From the values of  $v_{\infty}$ , the constant b of the Van de Waals equation has been obtained, and the values of  $v_{\infty}$ ,  $v_0$ , and b have been applied to the calculation of the pressure-volume relationship of isopentane, using a modified equation of state. The calculations agree with the observed values of Young even up to high pressures.

DIESEL-ELECTRIC LOCOMOTIVES —Experiments are being carried out by railway engineers in America and in several European countries on the use of Diesel engines in connexion with traction. In the Brown Boven Review for July, details are given of a Diesel-electric locomotive of 400 horse-power which has been built for the Strade Ferrate del Mediterraneo (Italy). This railway has about 600 miles of track in the provinces of Basilicata and Calabria, on which there are several long 6 per cent. inclines ments are also being made at the same time on special steam locomotives. It is specified that the locomotives must be able to draw a train weighing 110 tons up a 6 per cent. incline at a speed of 27 miles per hour. The engine of the Diesel locomotive is rated at 440 brake horse-power, but it can develop 500 B.H.P for short periods. The electric generator, which drives four ordinary traction motors mounted on the axles of the locomotive and two of the same type on the trailer, is directly connected to the Diesel engine by a rigid coupling, a special electrical system being used to minimise losses during the starting and stopping of the train. Experiments carried out on this locomotive by the Swiss manufacturers show that the mean consumption of naphtha per ton mile trailing load was about 0 068 pound. With steam service the fuel cost was practically twice as much. In the earlier experiments vibrations were pronounced owing to sudden variations in the load and owing to the machines being out of balance. The special balancing device now employed has notably diminished these vibrations. In special cases where no suitable electric supply is available these locomotives should prove useful.

REDUCTION OF MIXED OXIDES.—It has been stated (H. G. Wells, "The Outline of History") that "bronze is not only harder than copper, but the mixture of tin and copper is more fusible and easier to reduce." Thus it would appear that an oxide is Thus it would appear that an oxide is actually reduced at a lower temperature when in presence of a second metallic oxide. This subject has been investigated by W. Rogers, using a mixture of zinc and copper oxides. The mixtures were heated electrically to 300° in a glass tube through which a current of dry hydrogen was passing. The water formed in the reduction was collected in weighed tubes of calcium chloride. The data has been published in the Journal of the American Chemical Society for June, and it is obvious that all the zinc oxide in. the mixtures has been reduced. It is suggested that on fusing the oxides together, the presence of the second oxide prevents the units in the lattice structure of the other from arranging themselves in the normal way. This would cause the forces between the units in the structure to be altered and would result in a change in the reactivity of the oxides towards hydrogen.

## Pelagic Nemerteans.1

THE power of progressing through the water by swimming has long been known in the nemerteans; thus Nardo mentions it in Cerebratulus marquatus. Grube in Meckelia aurantiaca. De Quatrefages in Polia bembix, whilst more recently it has been described in Amphiporus pulcher, O.F.M., A. (Drephanophorus) spectabilis, De Quatref., Micrura fusca. McI., and Tetrastemma dorsalis. Abild. But the first truly pelagic nemertean was only brought into notice by Prof. Moseley during the voyage of the Challenger (1875). Now, through the labours of Hubrecht, Verrill, Craven and Heath, Brinkmann. Joubin, Gerarda Stiasny-Wijnhoff, and others, a long list of species from all the great oceans, except perhaps the Antarctic, demonstrates their wide distribution, though they are always thinly scattered, so that, as regards some, only one sex is known. Moreover, whilst the littoral nemerteans as a rule form two marked groups of the Enopla and the Anopla (the armed, with the mouth in front of the ganglia, and the unarmed, with the mouth behind the ganglia). the pelagic forms fall under a section of the armed. They are further distinguished by their comparatively short, flattened, and, in some, translucent bodies, the walls of which are in marked contrast to the firmer tissues of the littoral forms, for the almost gelatinous parenchyma is largely developed. Further, some possess a caudal fin, and a few, in addition, a lateral fin. The dorsal and the ventral longitudinal muscles with vertical bands are best developed. Eyes are often absent and sense organs few and peculiarly modified. The typical proboscis and its sheath, with the armature of the former leaning to that in Drephanophorus, is present, though no mention is made by either Prof. Brinkmann or the present author of the remarkable corpusculated fluid in its sheath Moreover, the males of the pelagic group carry their spermaries in the cephalic region with or without penes, whilst the females follow the littoral nemerteans in having the ovaries arranged along the body-in this case interdigitating with the alimentary cæca Lastly, some males are provided with a pair of muscular tentacles anteriorly.

The monograph of Mr. Wesley R. Coe has appeared nine years later than that of Prof. Brinkmann,2 and thus has the advantage of that masterly treatise, the classification in which the author follows, namely. the order Holopnemertini of Hubrecht being divided into the sub-orders Polystylifera and Monostylifera. The former has two tribes, the Reptantia, including the family Drephanophoridæ, whilst the Pelagia has

1 "The Pelagic Nemerteans" By Wesley R. Coe. (Memoirs of the Museum of Comparative Zoology at Harvard College, Cambridge, U.S.A.) Vol. 49, pp. 242+30 Plates. 1926 2 Vide Nature, July 4, 1918, p. 353.

no less than nine families. Further investigations and discoveries may perhaps lead to changes and simplification, but in the meantime order is maintained. The treatise contains a description of the pelagic nemerteans obtained (1) off the west coast of Mexico, Central and South America, and the Galapagos Islands, (2) those from the eastern tropical Pacific, and (3) those from the North-West Pacific Expedition.

The collections were originally taken in hand by the late Dr. Woodworth, but, on his death, the task fell to Mr. Coe After an introduction, in which the history of the pelagic group is outlined, the author gives a general survey of their structure under the head of morphological peculiarities. He differs from Gerarda Wijnhoff and Brinkmann in not reckoning the layers of the proboscis as if it were entirely evaginated, and he gives the anterior region nine layers, the most remarkable of which is the main nervous layer with its numerous longitudinal trunks and reticulations, the whole forming a system far larger than the two original (anterior) nerves, and which misled the reviewer in 1868 in thinking it a reticulated nonnervous layer. Like Brinkmann, he does not allude to the corpusculated fluid in the cavity of the sheath. nor is any light thrown on the function of this complex organ. He points out the importance in a pelagic form of the dorso-ventral bundles of muscle which are interdiverticular in position, and he agrees with Brinkmann that the muscular tentacles in the males of certain forms may be of use in holding the females whilst the sperm-sacs shed their contents, though in the littoral forms it is sufficient for the male to be in the proximity of a spawning female to cause an immediate issue of a cloud of sperms. He describes the subcutaneous sense organs as differentiated parts of the integument, and alludes to peculiar organs in connexion with the dorsal nerve in Neuronemertes aurantiaca-hinting that they may be phosphorescent organs, but such is unproved.

The contrast with the littoral forms in sense organs is striking, and yet it might have been expected that a free-swimming race was more in need of them. Mr. Coe devotes much attention to the minute structure of the reproductive organs both in text and illustration. He concludes with remarks on their food, habits, parasites, and enemies, and a detailed description of the 47 species in the collections. The whole forms a notable and independent contribution to our knowledge of the group in text, text-figures, and plates, and is alike creditable to the Museum and W. C. M the author.

<sup>3</sup> Trans R. Soc. Edin., vol 25, pp 305-433

## Tribute to Prof. H. F. Osborn.

THE seventieth birthday of Prof. Henry Fairfield Osborn, president of the American Museum of Natural History, was celebrated by the presentation to him of a Queen Anne cup made by Thomas Folkingham in 1711, and an illuminated book containing an address of congratulation, with the signa-tures of his colleagues and friends all over the world These signatures were made on individual slips of vellum and included nearly a thousand names. The design and decorations of the book were executed by Mr. William E. Belanske. Owing to Prof. Osborn's absence from the city on Aug. 8—the date of his birthday—the Committee in charge of the celebration waited upon him at Garrison on July 28 to make the presentation. They also invited Prof. and Mrs.

Osborn to be the guests of honour at a reception to be given them on Sept. 29, on which occasion the balance of the birthday fund raised by his friends, amounting in all to nearly seven thousand dollars, will be presented to Prof. Osborn for his research work.

The congratulatory address in the album presented

to Prof. Osborn reads as follows:
"On your seventieth birthday your colleagues and friends join to salute you, to congratulate you, and to express their delight in finding you radiant in health

and spirit, joyously carrying on your life work.

"We desire to thank you most heartly for your leadership in many fields. Drawing around you in the American Museum of Natural History a staff of explorers and co-workers who are animated by your

spirit and who gladly enrol under your banner, you liave penetrated to the uttermost parts of the earth and have brought its natural history treasures to the Museum To your unceasing labours, as Curator of Palæontology and as President, we owe the series of

Fig. 1—The inscription on the base reads "To Henry Pairfield Osborn, master builder, upon the occasion of his seventieth birthday, August 8, 1927, from his friends"

unique exhibition halls at the Museum, where countless visitors pass before an impressive panorama of extinct life Thanks to your sympathetic understanding the school children of New York and their teachers enjoy all the educational and emancipative opportunities of the Museum's School Service. And in the near future the Museum will also display still other imposing evidences of your constructive genius when the Roosevelt Memorial Hall and the Akeley

African Hall take their places in the assemblage of buildings devoted to science and education.

'We desire also to express our admiration of the creative, tireless spirit which, during a life crowded with administrative work, has produced a series of publications, covering many hundreds of titles and ranging from buef articles in Natural History to the great monographs on the titanotheres and the proboscideans now in press
"We congratulate you upon the many distinguished

honours that the highest scientific tribunals of the world have awarded to you in recognition of your services to science We join the great company of your readers in acknowledging our indebtedness for such classic works as 'From the Greeks to Darwin,' 'The Origin and Evolution of Life,' 'The Age of Mammals,' and 'Men of the Old Stone Age'

'Princeton University will not forget your services when in 1877 as co-leader with your life-long friend Professor W B Scott, you led the first Princeton expedition to the fossil fields of Wyoning; or when, after your return from your graduate studies at Cambridge University, you brought the Huxleyan

gospel of comparative anatomy to your pupils. Columbia University has reason to remember the great part you played in planning and guiding the Department of Zoology in its formative period, nor will your old students, either of Princeton or of Columbia, ever forget what new worlds you opened to them and showed them how to enter

"The New York Zoological Society owes to you thirty-one years of brilliant service as Chairman of the Executive Committee and later as its President.

"From many parts of the world, therefore, your friends unite to testify their appreciation of your services as a leader in biological science, in education, and in the highest ideals of citizenship.

"We congratulate you again upon this unique record of service. We delight in the admirable spirit of fairness, generosity, friendliness, and comradeship which you have shown, not only to your colleagues but to the least of your assistants. And we rejoice with your devoted wife and your sons, daughters and many grandchildren, that this seventieth birthday finds you with forces unimpaired, still planning, still building, under the inspiration of a dauntless optimism."

## The Conservation of Forests.

TORESTRY propaganda, by which is understood the endeavour to cultivate a forestry 'sense' in the people, has been in force for some time in the United States of America. The unrestricted lumbering under which so large a proportion of the forests of the country have been ruthlessly destroyed by axe, saw, and fire, led to the introduction of a forest service and forestry societies. It became recognised, however, that before any efficient protection of the remaining forest areas and the rehabilitation of portions of those destroyed could make any real progress, the people and the big lumbering companies would have to be educated as to the real meaning and value of the forest to the community and the nation. Various steps have been taken during the last decade or two, but progress in the direction desired was admittedly slow Latterly this crusade has been taken up with renewed vigour, and the methods employed are worthy, not necessarily of imitation, but at least of study and consideration; for propaganda of a similar kind is urgently needed if the new woods now being created in Britain are not to suffer from acts of negligence or worse at the hands of members of the community, entirely un-

acquainted with the objects aimed at in bringing into being this form of national (as also privately owned) property.

Two notes in the Daily Science News Bulletin issued by the Science Service of Washington, exemplify the type of propaganda in force in the United States. The language used is simple, technical terms being avoided, in order that the matter may be readily understood by the man-in-the-street. The first of the notes is entitled "Forest Trees Wage Fierce Struggle for Existence." A simple description of the forest is given, pointing out the different methods of growth of a tree growing singly or in a crowded forest, with examples of species which naturally grow in pure woods as against those appearing in mixture. The effect of the tree on the soil, and its demands and so forth, are simply treated of, the writer summarising his note with the remark: "A forest is a complete plant society in which the individuals compete in a struggle for existence, help each other by co-operating in keeping soil, moisture, and climatic conditions favourable to all, and are helped or hindered by thousands of subsidiary forms of life."

The second note, "Conserve Trees by Selective

Felling," has not the same application in Great Britain. For some years the U.S. forest officers have been striving to educate the lumberers and to reduce the damage and waste which have resulted from the lumbering of the forests in the past. Under these practices most of the young growth, which is not of size to be converted into lumber, has been recklessly destroyed whilst extracting the logs; moreover, large amounts of slash and refuse are left on the areas which, being so inflammable, usually catch fire. the fire often spreading to and destroying neighbouring valuable forests. The loss in this way, both in the United States and Canada, has been enormous. The present note is designed to show, from actual proof on the ground, that it is possible to lumber, i.e. to cut in a forest under a system of selective fellings by which the younger growth, or age classes, of the forest are left unharmed; and that this method actually gives better financial returns per acre, whilst subsequent fire danger is greatly reduced, since little slash remains. A further advantage of major importance is that additional fellings will be possible on the area when the young growth conserved has reached exploitable size. figures and results attained as given in this note merit the careful attention of the lumberer, not only in the United States but also in Canada.

## University and Educational Intelligence.

Cambridge.—Dr. F. J. W. Roughton, Trinity College, has been appointed lecturer in physiology and Mr. J. D. Bernal, Emmanuel College, has been appointed lecturer in structural crystallography in the department of mineralogy.

Free displays of films illustrating life in the British Dominions and Colonies will be given four times daily on week days and once on Sundays at the Imperial Institute, South Kensington, during September The programme is as follows: Sept. 4-7, Australia. New Zealand, and Canada; Sept. 8-10, South Africa and Australia; Sept. 11-14, South Africa, East Africa, Malaya, West Indies, Fiji, Sept. 15-17, India, Gold Coast; Sept. 18-21, Nigeria, Palestine; Sept. 22-24, Canada, British Guiana; Sept. 25-28, New Zealand, Sept. 29-Oct. 1, Canada and Australia. Teachers wishing to take organised parties of school children are advised to notify the Secretary, Imperial Institute, at least three days in advance of the proposed visit.

UNDER a recent regulation, the Board of Research Studies at the University of Cambridge now issues annually a volume of abstracts of the dissertations which have been approved for the research degrees (other than for the higher doctorates which are awarded on general published work at a later stage of a graduate's career). This volume will be useful as a guide to the ground covered by a piece of research where the complete work is only accessible in the University library. The need for it does not arise when the work is published in the standard scientific or literary periodicals, but the present pressure on the space of these journals makes it growingly difficult to publish work in full, and this summary of work may well fill a real gap. The summaries are arranged by faculties, and it may be of interest to note that the departments most largely represented are chemistry ten, physics and biochemistry six each, and botany five. On the literary side, history is the only faculty with a comparable output. Of the graduates, eight come from Caius and from Trinity, five from Emmanuel, while Corpus Christi, Jesus, King's, Queens' and Selwyn are all unrepresented. The research graduates are fairly evenly divided between graduates of Cambridge and graduates of other universities. The steady development of the research degree work at Cambridge is of considerable interest and importance.

'JUNIOR' colleges, offering the courses ordinarily taken during the first two years of the four-year college of liberal arts, are rapidly increasing in number in the United States, and are causing much attention to be focussed on the organisational relationship between the secondary schools and the universities and degree-conferring colleges This subject is dealt with m a closely reasoned and illuminating article contributed by Prof. Leonard V Koos of Minnesota to the May number of School Life, the official organ of the United States Bureau of Education. The main purpose of the article, publication of which is sponsored by the National Committee on Research in Secondary Education, is to show that present-day conditions point to the desirability of the integration of the junior college with the grades and work of educational units immediately below it—of definitely mcorporating it, in fact, in the secondary school system. Prof Koos first exposes the fallacies of the chief arguments which have been adduced for the separation of the public junior colleges from the grades of the 'high' school below, namely: the advantage in 'selling' the jumor college to the community, encouragement of the development of college life,' and safeguarding the standard of work He next points out that experience with other twoyear units, like the two-grade jumor high school and the normal school, has been unsatisfactory. His main arguments are that a review of reorganisation of secondary and higher education during the past hundred years shows the essential similarity of the purposes of education in high-school and juniorcollege years, and that their separation involves deplorable overlapping and waste of time.

The Carnegie Endowment for International Peace has Divisions of (1) Intercourse and Education. (2) International Law, and (3) Economics and History. The work of Division (1) during the year 1926 is described in a report, dated April 2, by its Director. Dr. Nicholas Murray Butler, who is also president of the Endowment and chairman of its executive committee. Of the total disbursements of the Division in the year, amounting to 363,663 dollars, the largest items were a grant-in-aid for the library building of the University of Louvain (50,000 dollars), and the expenses of a trip to Europe of American professors of international law and relations (63,312 dollars). Among the many activities for the promotion of which the rest of the expenditure was incurred were those of the International Relations Clubs, which are now established in 116 educational institutions in the United States. The members are chiefly undergraduates. The Division prepares for them fortughtly summaries of international events and supplies them with books and pamphlets. A handbook describing the work in detail is obtainable from the office at 405 West 117th Street, New York. The Division is responsible for the publication of "International Conciliation," a series of bulletins, begun in 1907, including texts of official treaties, articles by eminent statesmen, etc. The Centre Européen, maintained by the Division at a cost of 20,000 dollars yearly, published in January the first number of a quarterly, L'Esprit International. Its Directeur-Adjoint has recently conferred with the British Institute of International Affairs with the view of co-operation on lines already found effective in connexion with the Institut des Hautes Études Internationales and the Deutsche Hochschule für Politik, in which a Carnegie chair of international relations has been founded.

## Calendar of Discovery and Invention.

August 28, 1789.—The most magnificent of ighteenth-century telescopes, the great forty-foot effector built by Herschel at Slough, was begun in 785 and finished in 1789. It was built at the xpense of George III. Herschel gave a description of it in the Philosophical Transactions in 1795. The irst mirror was placed in the tube in February 1787 but was unsatisfactory; the second was cast in anuary 1788 but cracked, while the third and last was east a month later. On Oct. 24 of that year faturn was observed with it, but, said Herschel, not being satisfied, I continued to work upon it ill Aug. 27, 1789, when it was tried upon the fixed tars and I found it to give a pretty sharp image. Then he continues, "Aug. 28, 1789, Having brought he telescope to the parallel of Saturn, I discovered a ixth satellite of that planet, and also saw the spots ipon Saturn better than I had ever seen them before; to that I may date the finishing of the 40-feet telecope from that time."

August 29, 1864.—From his spectroscopic examination of the stars, Huggins turned to the examination of the nebulæ, and on Aug 29, 1864, he applied his spectroscope to a planetary nebula in the constellation Draco. It was then, to his surprise, that he saw a spectrum of bright lines, thus proving that the

nebula was a mass of glowing gas.

August 29, 1799.—Among famous steam-engine patents is that of William Murdock dated Aug. 29, 1799, for the D-shaped slide valve which in modified form is the commonest type of valve used in steam engines to-day. It took the place of the four poppet valves of Watt, who afterwards wrote. "When Mr. Murdock introduced the slide valve, I was very much against it, as I did not think it so good as the poppet valve, but I gave in from its simplicity."

August 30, 1576.—On this date the foundation stone of the famous Uraniborg, Tycho Brahe's great observatory on the island of Hven, was laid. One of the most remarkable instruments employed was the mural quadrant with which the altitude of the celestial bodies could be observed with far greater

accuracy than hitherto.

August 31, 1857.—The first of the great Alpme tunnels, the Mont Cenis, was begun on Aug. 31, 1857. Steam was originally used for driving the drilling machines, but, through Colladon, compressed air was utilised. The engineers of this great undertaking were Grattoni, Grandis, and Sommelier. The tunnel is 7½ miles long and cost £2,600,000. On Sept. 13, 1871, an experimental train was run through it and the tunnel was inaugurated four days later. The other great Alpine tunnels are the Simplon, the St. Gothard, the Lotschburg, and the Arlberg.

September 3, 1832.—From Oersted's discovery came those of Ampère, Arago, Sturgeon, and Faraday, while immediately after the publication of Faraday's work a group of inventors began to apply his discoveries. Among this group was H. Pixii, an instrument maker of Paris, who produced a magneto machine in 1831, and on Sept. 3, 1832, completed a machine with a commutator, in which a permanent magnet was revolved in front of a soft iron horse-shoe magnet with bobbins of insulated wire.

September 3, 1860.—In the splendid collection of meteorological instruments at the Science Museum, South Kensington, are many interesting records, including the first Daily Weather Report issued in England. This is dated "London. September 3, 1860." The particulars given are: Bar.: 30.13 in. Temp.: shade 58°. Wet bulb, 54°. Wind, W. Force of wind, 2. Cloud, 2. Sky blue. E. C. S.

## Societies and Academies.

#### PARIS.

Academy of Sciences, July 18-G Bigourdan. The differential determination of time with high precision .-- A Desgrez and J. Meunier The presence of lithium and strontium in the teeth and in human The existence of bones. Their chemical condition lithium and strontium as normal constituents of bones and teeth is definitely established. Lithium is present as phosphate and strontium as carbonate.—Léon Guillet. The properties of pure aluminium. Aluminium containing 99 8 per cent. of the metal is now commercially obtainable. Details of its electrical and mechanical constants are given. These do not differ greatly from those of the ordinary aluminium containing 0 5-1 per cent. of impurities.—Louis Ravaz was elected correspondant for the section of rural economy in succession to the late A. Balland—Georges Bourguignon Chronaxy of the muscles of the leg of the rabbit. Comparison with the chronaxy of the leg muscles of man in the normal state and in lesions of the pyramidal bundle.—Eugène Slutsky A limiting theorem relating to series of eventual quantities.—Edm Lahaye. A new method of mtegration of certain groups of differential equations. S. Stoilow · Continued transformations and Picard's theorem on integral functions—René Lagrange: Certam suites of polynomials. — Krawtchouk: The poles of meromorph functions.—D. Riabouchinsky. Fluid movements round infinitely near soluls.—Henri Mémery: The sun and the atmosphere. In attempts to find a relation between variations of solar phenomena (sunspots) and temperature variations in western Europe, results are more likely to be obtained by making comparisons each day than by using annual averages—J Struik and Norbert Wiener · The relativist theory of quanta.—H. L. Vanderlinden: The fine spectrum structure in the gravific field of the sun.-R. Anthouard. The conditions of discontinuity of discharge in gases Considering the tube through which the discharge passes as a condenser, a formula is developed which has been experimentally confirmed.—Max Morand. The distribution of the electric field in the dark space. E. Delauney: The atomic character of some properties of the X-rays. Experiments with irradiated mixtures of barrum chloride and strontium chloride show that the numbers obtained for the intensity of the fluorescence do not follow the additive law; the mtensity of fluorescence increases much less rapidly than the proportion of barum chloride -Ny Tsi Ze Changes in the optical properties of quartz under the influence of the electric field .- Paul Soleillet: The influence of the magnetic field on the polarisation of the resonance radiation of cadmium -Ch. Bouhet: The elliptical polarisation produced by reflection at the surface of liquids—A. Andant and E. Rousseau The resonance power of some metallic salts irradiated by filtered light from a mercury arc The phonomenon of resonance in the presence of a manganese salt described in a previous communication, is not an isolated experimental fact. The same phenomena are found in the presence of salts of magnesium, sodium, potassium, and uranium—P. Bonèt-Maury: The vaporisation of polonium Experimental results obtained by the method described in an earlier communication.—M. Wilmet: A method for the rapid estimation of hydrogen phosphide in a gas mixture. The gas is allowed to react with a solution of mercuric chloride and the hydrochloric acid produced determined volumetrically.-V. Auger and C. Eichner: A compound intermediate between

vanadium sulphate V<sub>2</sub>O<sub>5</sub> . n SO<sub>3</sub> and vanadyl sulphate -(VO) SO<sub>4</sub>.—W N. Ipatieff and B N Dolgof. The nydrogenation of tetraphenylmethane and p-oxytetraphenylmethane under pressure. With hydrogen under 80-100 atmospheres pressure and at 275°-285° C., tetraphenylmethane gives cyclohexane and tricyclohexylmethane hexylmethane p-oxytetraphenylmethane under similar conditions gives cyclohexanol, dicyclohexylmethane and some tricyclohexylmethane —Jacques de Lapparent. The texture of bauxites and their origin.—G Dubar: The metamorphic strata of Betchat (Ariège).-F. Dienert: The influence of the soil on the cooling of waters — E. Blanchard and J. Chaussin: The antagonism between chlorides used in large quantities and sulphates on the course of the development of wheat and oats.-J. Pien. The influence of calcium cyanamide on the reaction of the soil. Calcium cyanamide causes an increased alkalinity of soil for five to ten days: later, there is a slight reduction, but the final result is a clear variation of the pH of the soil towards alkalinity.-Th. Bieler-Chatelan: Chestnuts, ferns, and brooms. In spite of their preference for soils containing little or no chalk, the chestnut, fern, and Spanish broom may flourish in places where calcium carbonate renders the soil distinctly alkaline — P. Petit and Richard The saccharification of the dextrins.—Charles Pérez A protelian parasitism of Nectonema. -F. d Herelle and E. Peyre: Contribution to the study of experimental tumours.—Daniel Chevrier and Max Salles: The sterilisation of potable waters by electrolysis. The apparatus proposed consists of a metal tube forming the cathode with a fine platinum wire, placed along the axis of the tube, as anode. The voltage used is 110 to 120 volts.—Roger Douris and Charles Mondain: The differentiation of pathological sera by means of their dehydration figures.

#### CAPE TOWN.

Royal Society of South Africa, June 15 .- B. F. J. Schonland: The exchange of electricity between thunderstorms and the ground. Measurements were made in the summer of 1927 at Somerset East to determine the nature and magnitude of the exchange of electricity between thunderclouds and the earth. Seventeen active storms have been observed to pass over the station, all of which produced strong negative fields below them. Taking the average amount of electricity discharged in a flash to earth and the average interval between such flashes as 20 coulombs and 120 sec. respectively, the effect is equivalent to a current of 0.17 amp. The effect of point discharge was estimated by setting up a typical thorn-tree (Acacia Kaffra) on sulphur insulators and determining the average value of the current leaving the tree when the thundercloud was overhead. This amounted to 0.9 micro-amperes, averaged over an area of 50 sq. km. beneath the cloud. The total number of such trees in this area was estimated at 2.0 × 106, so that the upward discharge of electricity from them would amount to 1.8 amp The effect of the charge carried down by rain was negligible in comparison with that due to the flash and point discharges. The net result is a current of about 2 amp. between the bases of the clouds and the ground in such a direction as to give a negative charge to the earth.-J. H. Power: On the herpetological fauna of the Lobatsi-Linokana area.

#### GENEVA.

Society of Physics and Natural History, July 7.—R. Chodat and F. Mayer: The production of carotine in pure culture of green algae. It is possible to vary at will

calcium nitrate are added Maximum production occurs in a medium poor in assimilable nitrogen.-R. Wavre. Remarks on the stratification of the planets. The author demonstrates the following proposition: if the density  $\sigma\left(x,y,z\right)$  admits of first and second partial derivatives throughout the mass, the angular velocity and external surface being given. if a stratification exists with relative equilibrium without absolute rest, this stratification is unique.-Pierre Dine: General movements of rotation of the heterogeneous fluid mass and geodesy. The author proves the following fundamental propositions · whatever may be the law of flattening of surfaces with density constant, there exists an angular velocity of rotation, definite at each point of the mass and capable of maintaining its molecules in a state of uniform and permanent rotation. This angular velocity decreases constantly from the centre to the surface and from the pole to the equator, except perhaps in two extreme cases, one of which includes the particular case of Clarraut. In a heterogenous fluid in rotation, stratified in homothetic ellipsoidal layers according to Roche's law of densities, the square of the angular velocity of a molecule is a rational algebraic function of the co-ordinates of this molecule. —R Cherbuliez and G de Mandrot A new method of splitting up proteids. The proteid materials dissolve on heating (150°-200° C.) with acid amides. Acetamide extracts from casein, with a yield of nearly 100 per cent., a substance of the same percentage composition in carbon, hydrogen, and nitrogen, but possessing very different physical and chemical properties. The question arises as to whether there is a simple depolymerisation.—W. N. Schopfer: Researches on the influence of the nutritive medium on the formation of the zygotes in the heterothallic Mucorineæ. The study of Mucor hiemalis shows that in a sugar (maltose) nitrogen medium there exists, for the formation of zygotes, an optimum concentration characterised by a high proportion of sugar.— M. Gysin and C. Couchet: Remarks on the methods of analysis of platinum minerals. The authors have submitted to a very detailed control Thuringer's method and that used in refineries. Neither method gives a complete separation of iridium.—A. Naville: Fertilisation and the chromosome cycle of Chloromyxum Leydigi. Studying the evolutive cycle of Chloromyxum Leydigi, the author shows that in this species there should be two successive fertilisations, one isogamous after the formation of the spore, the other anisogamous before the formation of the spores This hypothesis reconciles the two theories concerning the fertilisation of the Myxosporidieæ and possesses the advantage of explaining all the figures of Keysselitz.

the quantity of carotine produced by algae in a nutritive

medium of glycogen to which suitable proportions of

## Man and his Ancestry.

SIXTY-NINE years ago. at the British Association assembled in Leeds, Sir Richard Owen, the first anatomist of his age, poured scorn on the theory of man's descent from an anthropoid stock, a theory which the president of to-day, another distinguished anatomist, regards as unshakable. Since the publication of "The Descent of Man" in 1871, we have come to know more than a little of the precursors of Homo sapiens, and this direct evidence of anthropoid ancestry has been corroborated on many sides. Thus the blood of man and that of the great anthropoid apes gives almost the same reaction; in the anthropoid brain are to be recognised all those parts which have been magnified in man, we find the same vestigial structures or 'evolutionary post-marks' in apes and in ourselves, the embryos of the two stocks develop along the same main path; the anthropoid mother fondles, nurses, and suckles her young in the human manner. "The fundamentals of Darwin's outline of man's history remain unshaken."

With his characteristic frankness, Sir Arthur Keith admitted, in his carefully restrained and vividly phrased address, that we have to correct some of the early blunders. Thus man's descent has not been in a straight line, one offshoot has given rise to another after a fashion that might be compared to a cymose inflorescence. "It is among a welter of extinct fossil forms which strew the ancient world that we have to trace the zigzag line of man's descent." We no longer expect to find an orderly file of extinct stages in which every part of the body becomes, as we advance, a little less ape-like, a little more man-like. For we know that this en bloc orderly advance is not usually disclosed in evolutionary series. While one part of the body moves forward, another often lags behind.

The distinctiveness of man, even of tentative men, Hominids before Homo, is in his big brain. Is there any light on the conditions of this advance? Being, as became a president, in a cautious mood, Sir Arthur Keith declared that there is not as yet any explanation to offer, yet he proclaimed with no uncertain voice that "Man has reached his present state by the action and reaction of biological forces which have been and are ever at work within his body and brain" Much depends on what is meant by "biological forces," and we wish to linger over the crucial question: How did man get his big brain?

Sir Arthur referred to Sir Ray Lankester's observation that an increase in the size of the brain

occurred not in the ancestors of man alone, but in diverse branches of the mammalian stock in the Miocene period. Was there at that time some environmental stimulus prompting cerebral advance, or was it the outcome of an age-long evolutionary trend in the course of which brams had largely superseded brawn? Also, is there not some elucidation in Prof. Elliot Smith's view, supported by an eloquent series of brains, from tree-shrew to ape, that the arboreal habit put a premium on variations in the direction of an increased neopallium, with special enlargement of particular areas, such as those concerned with visualising and manipulating, with a corresponding decrease of others, notably the olfactory centre? When, also, the uplift of the Himalavas and the shrinkage of forests brought the precursors of man back to solid earth, enriched by an arboreal apprenticeship, would there not be many a reason why variations in the direction of better brains should be fostered? For these tentative men would find themselves in a new environment, with new competitors, and therefore with increased need for standing by one another in little troops. But the beginning of society served as a shield over variations which had much less chance under an each-for-himself regime, and over helpless stages of early infancy and old age, the former ensuring a better future through education, and the latter a conservation of traditional wisdom.

Would it not be in these groups of families that the transition was made from words to language, that is to say, to the expression of simple judgments by means of socially significant imitated sounds. As these auditory symbols were added to visual ones, an incalculable addition was made to the capacity for ideation. became much easier with words as counters. gradually the meshes of the selective sieve were altered to favour variations in cerebral capacity. That the origin of these variations remains obscure is true enough, but that is not a particular puzzle affecting the ascent of man; it applies to all emergences of the distinctively new. The frequency of cerebral variability in man is obvious in almost every family; the problem of the origin of variations is relevant throughout the whole of animate Nature.

As animals become cleverer, it is increasingly possible for them to have smaller families; other things equal, an economy in reproduction has survival value. But the reduction of the number of offspring, made possible by quickened wits and enhanced parental care, favours family life and creates an atmosphere which is selective towards No. 3018 Vot. 1201

Carlos Carlos Anti-

variations in the line of affection, kin-sympathy, and conversation. All these evolutionary processes of the subtler type work round in virtuous circles. Again, we cannot but inquire, on a more physiological level, whether there was not much shrewdness in the old suggestion of Robert Chambers, that prolonged gestation was a factor in evolution If the conditions of life, such as sociality or seclusion, as in elephants and Peripatus respectively, allow of prolonged gestation, there is obviously an opportunity for the offspring being born at a relatively advanced stage, able very soon to fend for itself if need be. One may contrast the newborn foal with the new-born kangaroo shunting back of the developing period into the antenatal arc of the life-curve allows of a safe and sequestered differentiation of the nervous system without very much being asked of it, allows of a suppression of much of the repertory of instinctive capacities, so necessary when the creature is born at a less finished stage, and allows of the more successful development of plastic intelligence.

The prolonged infancy, so characteristic of Primates, would operate like the prolonged gestation in allowing a longer period for brain development before responsibilities intrude. Even if the number of cerebral neurons does not increase after birth, there are ramifications and linkages to be The prolonged infancy, increasingly established ensured by the incipient sociality with its division of labour, would react on the parents and help to form a sieve that favoured the wiser and kindler There is much truth in Rousseau's saying: Man did not make society, society made man.

These are some of the suggestions that might be made towards an elucidation of the problem of anthropus, with his small and simple brain, the advance was not initial, but after a footing in the struggle for existence became surer. It may of course be said that variations in the regulative system—in hormone production in particular stimulated brain development, and were associated with temporal variations in the relative length of the antenatal and infantile arcs in the trajectory of life; and Sir Arthur evidently looks to hormonekeys to open locks to which they have not yet been fitted by the evolutionist ' But our suggestion is that more must be made of the psychical and social factors in man's emergence.

What seems to us most distinctive in Sir Arthur Keith's position is his suggestion that racial evolution will become more intelligible when it is seen in the light of individual development. It is traditional to consider ontogeny in the light of phylogeny, and that illumination cannot be dispensed with. but there has not been adequate consideration of phylogeny in the light of ontogeny. "When we have discovered the machinery of development and of growth we shall also know the machinery of evolution, for they are the same." Slight changes in developmental rate and rhythm, slight oscillations in the co-ordinating and regulating influences, slight relaxations and tightenings of hormonic control, and the developing organism is altered, as we know, both for good and ill. We understand Sir Arthur to suggest that these developmental variations have furnished the raw material which the processes of selection have sifted

There we must walk warily. Is it not the case that variations often appear in embryos before there is any differentiation of endocrinal glands, and in many organisms where hormones are experimentally unknown? Moreover, all the wobblings in developmental regulation, whether hormonic or otherwise, have themselves to be accounted for If they are environmentally induced, will it not imply postulating the hereditary transmission of acquired modifications, or a remarkable persistence of the same environmental influence during the ages in which a particular trend of evolution—such as the differentiation of the neopallium—has been in progress?

It may be suggested that a deeply saturating environmental influence, climatic for example, may affect the germ cells along with the body in such a way that the regulative system is perturbed. But unless we can define these environmental influences, we are almost back to Darwin's confession of ignorance, unless, indeed, we are led to an almost providential view of what has been called 'the fitness of the environment.'

It cannot be doubted that a deepened knowledge of development—especially through experimental embryology—will throw light on evolution, but it is going a long way to say that their problems are the same. The germ cell starts with a repertory of initiatives, including not only factors but also regulations of these, and this repertory presupposes evolution. Again, if an individual embryo suffers some regulative perturbation in a non-fatal degree, it can within limits effect automatic adjustments, but this is very different from the active way in which many an organism plays its hereditary cards in relation to alterable circumstances. There is more than machinery when a higher animal shares

in its own evolution, even sometimes selecting its environment. In the evolution of the higher animals at least, the personality of the creature counts and though the personality may doubtless be influenced by the hormones, this does not alter the fact that the organism plays its own game for better or worse. This is what Prof. James Ward was driving at in his emphasis on what he called 'subjective selection'

Sixty-nine years ago Sir Rıchard Owen told his Leeds audience that mankind required an altogether separate order in the animal kingdom, but what Sir Arthur Keith followed Darwin in emphasising was man's solidarity with the rest of creation. Few, we think, will read the presidential address of 1927 —dignified, responsible, and pithy—without admitting the convincingness of the evidence that "Man began his career as a humble primate animal" There is danger perhaps lest we underestimate the magnitude of this hard-won conclusion and its mysteriousness For we must think not only of man primitive and tentative, but also of man as minister and interpreter of Nature, man as poet and painter, discoverer and saint. We must estimate everything by its best, and then what a piece of work is a man!

Using the word emergence does not solve any problem, but it expresses a mode of becoming that has often occurred. A combination of two gases, oxygen and hydrogen, results in the production of water with entirely novel and in some measure unpredictable properties; so there has been in organic evolution a repeated origin of new types, now an insect and again a bird—resultants that seem too big for their components. Lloyd Morgan uses the word 'emergence' to emphasise the difference between an additive resultant and an outcome that is a new synthesis.

Without going back to the position of Alfred Russel Wallace, Darwin's magnanimous colleague, that man's higher qualities demand "some origin wholly distinct from that which served to account for his animal characteristics—whether bodily or mental," without seeking for this dualistically in some special 'spiritual influx,' such as operated also at the origin of living creatures and of consciousness, we may see some truth in the idea of man's 'emergence' and apartness. He was an organic genius, a new synthesis, if ever there was one; no mechanical additive resultant, but a vital new creation, though coming but slowly to his own; not involving any breach of continuity, but making a fresh disclosure of the riches of reality—and continuing to do so. Into the fabric of humanity

came many strands of many mammals, but some threads were new and the pattern was new, and it continues to evolve—But this 'emergence,' it may be said, savours of the magical,—an outcome too big for its antecedents! Yet is this not one of the commonest of fallacies? We are not slow to regard man in the light of evolution, but we have scarcely begun to envisage evolution in the light of man.

To return to Sir Arthur Keith's address—it stands out as a discourse instinct with the scientific spirit; it is a fine piece of scientific tactics—to abstain, except once, from speculative discussion of factors, so that the facts might stand forth in their stability; and it is a beautiful piece of English prose, as one knew beforehand it would be, for "Le style, c'est l'homme même"

## Mechanics of the Atom.

The Mechanics of the Atom. By Prof Max Born.

Translated by Dr J W Fisher and revised by Dr D R. Hartree. (International Text-Books of Exact Science.) Pp. xvi+317. (London. G Bell and Sons, Ltd., 1927.) 18s net.

TYTHEN Prof. Born published his "Vorlesungen über Atommechanik" two years ago, atomic theory was beset with difficulties which, as one writer has remarked, were strongly suggestive of the epicycles of Ptolemaic astronomy. It was obvious that there was some inherent defect in the theory and nothing less than a radical change of outlook was required. It seemed impossible to make a quantitative determination of intensities of spectral lines on the basis of accepted mechanical pictures of atoms Nor could the theory of dispersion be considered satisfactory, as it depended on a transcription of the various steps in the ordinary classical theory and was not built up logically on the fundamental postulates of the quantum theory.

The fundamental step in resolving these, among other, difficulties was taken by Heisenberg soon after the appearance of Prof. Born's book. He abandoned the usual methods of calculation in terms of mechanical frequencies and such features of mental pictures as were not amenable to observation; in fact, he virtually abandoned the usual pictures in space and time whereby an electron is here and here only at one instant, and there and there only at the next. He introduced instead a quantum mechanics involving manifolds of quantities—matrices as they were afterwards shown to be—which depended on observable transition frequencies and not on unobservable mechanical (or

orbital) frequencies—The atom must henceforth be considered as a whole and not as a collection of individual particles each with a separate identity. The importance of the new step was immediately recognised and led to a rapid development of a rational, self-contained system of quantum mechanics with a remarkable simplification of the essential quantum conditions.

The theory was only a few months old when a new and independent set of investigations was published by Schrödinger, who introduced another point of view. Schrodinger re-emphasised the analogy between dynamics and geometrical optics, already pointed out by Hamilton in his first researches on dynamics But he went further than Hamilton in that he attempted to extend the analogy between mechanics and optics to take in the concept of waves, which had proved so necessary m optics to explain interference and diffraction phenomena. Schrödinger found the appropriate generalisation of ordinary Hamiltonian dynamics, and, beginning with the simple hydrogen atom, applied it with astonishing success to a number of atomic problems

After the essentially mathematical nature of the matrix mechanics, the new treatment by Schrödinger came as a pleasant relief to many physicists, as it, at any rate, held out some prospect of the re-establishment of physical pictures of atomic processes. Although in this theory material particles are replaced by wave systems, a definite localisation of electric charge in space and time seems possible, and this with the aid of ordinary electrodynamics accounts for the frequencies, intensities, and polarisation of the light emitted by atoms without the introduction of a number of correspondence and selection principles. Furthermore, the theory accounts for the phenomena of absorption, dispersion, and scattering in a more. rational way than was possible with the old quantum theory.

The equivalence of the matrix and wave mechanics has now been established (principally by Schrodinger himself), and attention has latterly been directed to the physical and philosophical implications of these two aspects of atomic theory. The relation between the Schrödinger waves and electrons seems analogous to that between radiation and light quanta. On the wave theory, one cannot answer the question as to how a particular particle moves, but one can instead find the probability of its moving in any specified direction. Whether or not this means the abandonment of the law of causality in atomic problems is a question

which has received considerable attention recently, but is likely to remain for some time unanswered

In the hands of Prof. Born the new theory has vielded a satisfactory explanation of the results of Franck and Hertz on electronic collisions with atoms, and has led to a qualitative explanation of the experiments of Dymond on electron scattering. While incompetent to deal with the life history of any single electron in collision, the new theory deals successfully with a stream of electrons and may be regarded as a singular fusion of mechanics and statistics.

In the light of the new work and the abandoning of cherished mechanical pictures of atomic processes, such terms as position and velocity of electrons require examining anew. Only when methods have been devised for their experimental observation will they be of physical significance. The possibility of making such determinations has recently been considered by Heisenberg, and has led him to important conclusions regarding the possibility of making simultaneous determinations of the position and velocity of a free electron. It seems that here, too, Heisenberg has opened up a new line of thought, and interesting developments may be expected in the near future.

In view of these recent developments in the mechanics of the atom, it may well be asked whether any useful purpose is served by the translation of Prof. Born's book published two years ago. The answer was given by Prof. Born in the preface to the original German text, when he said.

This work is deliberately conceived as an attempt, an experiment, the object of which is to ascertain the limits within which the present principles of atomic and quantum theory are valid and, at the same time, to explore the ways by which we may hope to proceed beyond these boundaries. In order to make this programme clear in the title, I have called the present book 'Vol I', the second volume is to contain a closer approximation to the 'final' mechanics of the atom."

The material for Prof. Born's second volume is now to hand, and students of theoretical physics will await with some impatience the completion of the task which Prof. Born has set himself. Meantime, the first volume serves as an excellent introduction to recent developments. It provides an account, at once concise and lucid, of the general dynamics of Hamilton and Jacobi, with just that special orientation towards atomic problems for which there has been a long-felt want. It introduces the reader to just those theorems of dynamics which have proved so essential in the recent developments of the new quantum mechanics.

The translation has been carried out with great care under the supervision of Prof. Andrade, who has himself contributed one of the most valuable of recent introductory treatises on atomic structure. The book shows signs of a painstaking revision, with the result that the reader is presented with a translation which is accurate without a too slavish adherence to the original text.

There are one or two minor departures from the German text, which have been necessitated by the publication of new experimental work since the appearance of the original edition. Some modifications have been made in the early paragraphs concerning the mechanism of radiation to take into account the experimental results of Geiger and Bothe, and of Compton and Simon, and there has been a modification of the derivation of the Rydberg-Ritz series formula on the lines suggested by Bohr

The publishers are to be congratulated on their enterprise in producing a translation of this book, and on the efficiency with which they have carried out their task. The binding and printing are alike excellent.

J E L-J.

### Cambridge Biographies.

Alumni Cantabrigienses a Biographical List of all known Students, Graduates, and Holders of Office at the University of Cambridge, from the Earliest Times to 1900. Compiled by Dr. John Venn and J. A. Venn Part 1: From the Earliest Times to 1751. Vol. IV.: Saal-Zuinglius. With an Appendix containing additional Information relative to previous volumes. Pp v+538 (Cambridge. At the University Press, 1927.) 150s net

THIS volume completes the monumental record by the late John Venn and his son, of the sons of Cambridge up to the year 1750, it contains 42 pages of additional information in supplement to the earlier volumes. The welcome announcement is made in the preface that the Syndics of the University Press have undertaken to see Part 2 also of "Alumni Cantabrigienses"—for the years since 1750—through the press

There are not so many famous names in science in the present volume as in the earlier ones—we note John Wallys, one of the founders of the Royal Society; Samuel Wegg, its treasurer for thirty-four years, Edward Wright, of Mercator's projection, Francis Willoughby, the distinguished naturalist, fellow traveller with John Ray: William Turner, the scientific pioneer in botany; Robert Smith, founder of the Smith's prizes, Nicholas

Sanderson, who lost his eyesight in infancy from smallpox, yet became later Lucasian professor, and William Whiston, Newton's successor in the same chair, who was banished from the University for his Arian views — We note that T Tudway, organist of King's and professor of music, was deprived of his chair for making puns on the queen, but he afterwards recanted and was readmitted

Robert Taylor, who perfected the cure of ague by quinine and was physician to Charles II, is one of many distinguished medical men who figure in the volume, and it is noteworthy how frequently the letters FRCP, F.RS are coupled together. Another prominent group are the divines, among whom may be mentioned William Tyndal, the translator of the Bible. Archbishop Whitgift, Samuel Wesley, father of John and Charles, and Thomas Sheppard of Emmanuel, in honour of whom Cambridge, Massachusets, was so called. The names of Edmund Spenser, John Suckling, and Edmund Waller remind the reader of the place of Cambridge as a nursery of English poetry, while Laurence Sterne and W. Stukelev recall other literary activities.

Echoes of bygone times are found in the record of Job Tookey, admitted at the age of thirteen years in 1658, removed after a fortnight, apprenticed to a grocer in Cheapside and later sent to sea, or of Henry Sumpter, sent from King's College to New College, Oxford, where he was thrown into a cave under the College where salt fish was kept—and died not long afterwards A more modern touch is sadly supplied by F. Sterling, Fellow of Jesus, killed in the War in Flanders in 1692 of Sir Robert and Horace Walpole; of Thomas Wentworth, Earl of Stafford; and of George Villiers, Duke of Buckingham, recall the historical background; while Richard Whittington, Lord Mayor of London, figures in the volume as one of the early benefactors to the University Cambridge owes a deep debt of gratitude to the authors of these volumes for their zeal, learning, and accuracy, and the services of the University Press in publishing them must not be forgotten.

# The Origin of the Week.

The Week: an Essay on the Origin and Development of the Seven-day Cycle. By F. H. Colson. Pp. viii + 126. (Cambridge: At the University Press, 1926.) 5s. net

THE seven-days week is a division of time which has long been in general use, and is commonly believed to have come down to us from

No. 3018, Vol. 120]

at least the time of Moses, but why or how the days have become associated with the planets—the word planet is here used as understood by the ancients—is not so generally known. Mr Colson's book supplies an immense deal of information on this point, and is obviously the result of a great deal of study and research

The author's purpose is to show that our present week is a combination, which took place within the Roman Empire, of two distinct systems—the Jewish week and the 'planetary' week The former had long been familiar to the Romans, but the latter, as he shows, cannot be traced back much earlier than the beginning of the Christian era, and was due to the development among the masses of astrological ideas as to the influences of the planets.

The accepted order of the planets according to their distances from the earth, starting with the outermost, was Saturn, Jupiter, Mars, Sun, Venus, Mercury, and Moon, but this order is not at first sight evident in the sequence of the names There are successive jumps over two planets, but a suggestion of Dion Cassius is accepted as probably correct, namely, that the planets were supposed to rule successively for one hour at a time. Thus starting with the first hour of Saturn's day (Satur day) Saturn itself was regent, but Jupiter presided over the second hour, Mars over the third, and so forth, which brings the first hour of the second day under the regency of the sun (Sunday). Similarly, the opening hour of the third day will be ruled by the moon (Monday), and the order of the names throughout the week is thus readily explained It is suggested that originally the point of contact between the Jewish and the planetary weeks was the Sabbath. It is shown that by the beginning of our era the idea had become widespread that that day was Saturn'sday, and this may perhaps have given the planetary week its starting point

Among other matters of interest in the book we find the discussion of such subjects as the week in the New Testament and the early Church, and the establishment of Sunday as the Lord's Day. With reference to the latter, while acknowledging that by the second century the first day of the week had acquired an undoubted sanctity as that on which the Resurrection took place, the author concludes that we owe our religious and civil Sunday to the combination of two factors, namely, "the immemorial familiarity of the Jewish Christian with the Sabbatical week, and the recent familiarity of the Gentile Christian with the

planetary week" There is also an instructive one and all excellent. The description of bonito chapter on the week in northern Europe, and the names of the days in various European languages are collected together into five groups in the appendix.

The book is extremely well written and contains much information not readily accessible to the ordinary reader Its usefulness would have been still further enhanced by the addition of an index or a synopsis of the chapters.

### Our Bookshelf.

Treatise on Sedimentation. Prepared under the Auspices of the Committee on Sedimentation, Division of Geology and Geography, National Research Council of the National Academy of Sciences By William H Twenhofel and Collaborators. Pp xxv + 661 + 38 plates. (Baltimore, Md. Williams and Wilkins Co. London: Baillière, Tindall, and Cox, 1926.) 34s net.

The treatise is a bold and ambitious attempt to present a comprehensive statement of our present knowledge of sediments and the processes which control their formation and development From the point of view of work accomplished in America, it may be satisfactory as a preliminary basis for the discussion of future researches, but it is unfortunate that many British and European contributions to the subject matter should have been overlooked. The committee on sedimentation has apparently realised this source of weakness in their earlier work, for Prof L W. Collet has now been added as a European representative. In the treatise itself the lack of international proportion is shown by the fact that there is only one nominal reference to the far-reaching work of Prof P G H. Boswell, and that to the statement that "sand is predominantly composed of quartz grains." On p 629 one of Boswell's memorrs is wrongly attributed to Crook, but in compensation Crook's name does not appear in the index.

While it is in many parts admirable, the treatise is clearly far from being the authoritative work we might reasonably have expected. The necessity for further studies of environment of deposition and of diagenesis is revealed by the striking absence of precise knowledge in these fields of geological endeavour.

 $\begin{array}{lll} \textit{Melanesians of the South-east Solomon Islands}. & \text{By} \\ \text{Dr. W. G. Ivens.} & \text{Pp. } \sin + 529 + 15 \text{ plates.} \\ \text{(London: Kegan Paul and Co, Ltd., 1927.)} \end{array}$ 30s. net.

This book is very well written, in simple vivid language, and the author is at his best in the descriptions of particular customs, ceremonies, and beliefs. The chapters on sexual life, betrothal, and marriage, the accounts of fishing and gardening, of feasts and dancing, of warfare and magic, are

fishing, so characteristic of the Southern Solomons, is of outstanding literary merit and scientific interest

The abstract subjects, such as kinship and legal or economic organisation, suffer from a weak grasp of sociological principles. The table of kinship nomenclature is well-nigh worthless, in that it gives the native words for English appellations mstead of giving a sociological analysis of the native terms. The author is right in correcting the late Dr Rivers (on p 59) on the use of personal names between relatives in some parts of Melanesia, a custom which is by no means confined to Dr. Ivens's area But when he adds that "relationship terms in these places (Sa'a and Ulawa) do not connote social duties," he contradicts his own evidence, and his mistake is due to an obvious misunderstanding of Dr Rivers's words and ideas. Equally misleading are certain generalisations about native shell money

On the whole, however, the book is a valuable contribution to Melanesian anthropology: it provides very attractive reading, and is magnificently filled with illustrations in colour and black and white, with diagrams and

Practical Psychology: Human Nature in Everyday Life. By Prof Edward Stevens Robinson. Pp xii + 479. (New York: The Macmillan Co., 1926.) 7s 6d.

This is a simple presentation of the main features of psychological science aimed at bringing out the relations of its principles to the personal life of the student. As the study of human nature, psychology deals with human behaviour as well as with mental life in the abstract; and, for practical purposes, a knowledge of behaviour and its sources is the more important aspect of the two. Though most people know some psychology (since they carry human nature about with them and can scarcely fail to observe it), science is necessary to approve, correct, or reject popular notions as to the working of human nature, especially when such notions are employed in any attempt to alter or perfect its working. Chapters on the connexion between human nature and body are followed by a fairly complete discussion of all the topics dealt with in elementary psychological textbooks.

The matter is clearly presented, with simple problems suggested at the end of each chapter and references for further study appended The book substantiates its claim to be practical throughout, and needs no educational background "greater than is likely to be possessed by a student in the latter part of the high school course." As an indication of the general method followed by the author, one of the problems set at the end of the chapter on personality may be quoted. "No personality is perfect. What steps might you take to make yourself a more effective individual  $^{\imath}$  " Materials for its solution, as for that of the other problems set, are given in the text.

Faune de France 13 Deptères (Brachycères)

(Stratiomyridæ, Erennidæ, Conomyridæ, Rhagronidæ Tabanidæ, Codidæ, Nemestrinidæ,

Mydaidæ, Bombylidæ, Therevidæ, Omphralidæ)

Par E. Séguy Pp 111 + 308 55 francs 14

Deptères pupipares Par Dr L Falcoz Pp 64

12 50 francs (Fédération française des sociétés
de sciences naturelles Office centrale de faunistique) (Paris Paul Lechevalier, 1926)

We welcome these two additions to that excellent series the 'Faune de France' Part 13, by M  $\to$ Séguy, deals with all the families of the so-called Platygenia group of the Brachycera with the exception of the Asilidæ This family, along with the Orthogenia, will presumably form the substance of a future volume Part 14, by M L Falcoz, is concerned with the group Pupipara, and we are glad to note that the Braulidæ are no longer included among the latter These treatises are more especially intended as guides to the identification of the groups concerned, and for this purpose concise family, generic, and specific keys are provided. Further and more detailed characters will be found under each species together with a summary of its geographical range Special mention needs to be made of the very large number of line figures illustrating important diagnostic features The biology of these insects is also by no means neglected, and, wherever information exists, some account of larval and pupal structure and habits is given. These two parts are well up to the standard of their predecessors, already noticed in these columns, and they can be recommended to all dipterists as well as to the general entomologist.

Aeronautical Meteorology. By Wilhs Ray Gregg. (Ronald Aeronautic Library) Pp. xii+144+11 plates. (New York The Ronald Press Co, n d.) 2.50 dollars

The aeronaut's need of a knowledge of weather is vital, but the ordinary meteorologist when trying to provide for it finds it difficult to put on one side the conventional modes of treatment and to remember what is really wanted. thus when describing the upper winds at any place, he is tempted to give the mean wind direction at successive heights, instead of a table of the relative frequencies so that the pilot may know the likelihood of a favourable wind.

However, Mr. Gregg has admirably realised the situation. After an account of the general circulation and of the methods of observation, he naturally deals with American conditions, discussing the vertical structure of the air (but the constancy of e P on p. 31 should be explained), the change of winds with height and gustiness, fogs and clouds (the photographs of these being excellent), visibility, thunderstorms, cyclones and anticyclones, forecasting, and flying over the North Atlantic and the north polar regions. His moving thunderstorm' corresponds with what is called in England a line squall, but its width is given as 40 to 50 miles, the length being 150 to 200 miles. The chapter on cyclones is essentially practical, though interesting theoretical questions

are raised by the predominance of rain to the N.W. of the centre instead of to the S.W. and S.E., which the Bjerknes theory suggests. We wish that such a book were available for those under British conditions.

Field Astronomy: for Engineers and Surveyors
By Prof D Clark Pp viii + 164 (London
Constable and Co., Ltd., 1926.) 10s 6d net

This manual provides a concise summary of the astronomical principles and methods of observations employed by surveyors and engineers when requiring absolute positions on the earth's surface in the course of survey work The contents are lucidly arranged in three chapters, dealing respectively with principles, instruments, and observations Good type, explanatory diagrams, reproductions of the various instruments used, a number of worked examples, and a bibliography contribute materially to the value of the book. The description of the methods for determining longitude includes full details of the reception of radio signals used for this purpose. Consonant with its title, the book is of handy pocket size. It should be of great use both to engineers, who wish to have the working details of astronomical observations used in the field, and to university students of surveying and geodesy

A Handbook of Renal Surgery By F McG Loughnane. Pp xiv + 210 (London Longmans, Green and Co , Ltd , 1926 ) 10s. 6d net

In his preface to this book, Mr Loughnane tells us that it is intended for the use of general practitioners and students The reader will therefore not expect detailed descriptions of kidney operations, which are largely in the hands of specialists The author concerns himself almost entirely with the investigation of surgical diseases of the kidney, and his accounts of diagnostic methods are clear and complete The number and quality of the radiographs with which the book is illustrated demonstrate the value of X-rays in this branch of surgery, and it is evident that there are few surgical conditions of the kidney which do not require preliminary radiological investigation. There is a useful chapter on the estimation of renal function

Chambers's Encyclopædia a Dictionary of Universal Knowledge Edited by Dr David Patrick and William Geddie New edition Vol 9 Sacrament to Teignmouth. Pp 1v + 904. (London and Edinburgh: W and R Chambers, Ltd.; Philadelphia J. B Lippincott Co, 1927) 20s. net.

This useful encyclopædia is now nearing completion. The present volume contains a number of new articles, while the others have been thoroughly revised. Several of the articles are of considerable length and give practically all the information about their respective subjects that the reader or student could desire. The free use of illustrations and diagrams adds to the value of the work. All the longer articles have numerous references to literature. There are eight coloured maps by Bartholomew with new boundaries clearly shown.

### Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can be undertake to return, not to correspond with the ariters of rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

# An Effect of Sunlight on the Altitude of Aurora Rays.

ON Sept 8, 1926 between 21° 30° and 22°, Greenwich mean time, I saw from Bygdo, near Oslo, a remarkable aurora in the west. It had the form of a portion of a feeble arc of grey violet colour, stretching upwards from the horizon about 40°. Later on this arc changed into a diffuse mass sharply limited on its south border.

Simultaneously, this aurora was very carefully observed from the Lerwick observatory as faint streamers on the northern, eastern, and western part of the sky up to zenith

I was fortunate enough to have two of my aurora stations in action. Bygdo and Oscarsborg, mutual distance about 26 kilometres, and I obtained of this remarkable aurora a series of photograms of the greatest interest. The measurement and calculation of the photographic plates will appear shortly in Gerlands Bertrage zur Geophysik and I will here only mention the principal results.

The arc appeared on the plates as a curtain of rays which were difficult to distinguish visually, and this curtain was situated over and to the north-west of the Shetland Islands at the quite unusual height of 300 to 500 kilometres. The diffuse form which ended the aurora display probably reached the immense height of more than 1000 kilometres. This high curtain was essentially different from all curtains measured in southem Norway from 1911-1922, m fact, these curtains generally had a vellow-green colour and were situated from 80 to 200 kilometres above the earth.

The situation of the cuitain fai in the west, some hours after sunset, led me to the supposition that it was perhaps illuminated by the rays of the sun My assistant. Ragnyald Wesoe, made at my request the necessary calculations, and the hypothesis was verified the amora

was situated in that portion of the upper atmosphere directly illuminated by the sun.

It was now an interesting question to know if the aurora rays, measured during the years 1911 to 1922 and of unusual altitude from 400 to 800 kilometres, were also exposed to the rays of the sun. Mr. Wesoe calculated the height of the daik portion of the atmosphere for each ray whose situation had been calculated from photograms <sup>1</sup> and the results are as follows.

The rays situated in the interval from 400 to 800

kilometres above the earth were all exposed to the sum's rays, and of those stretching from 100 to 400 kilometres, about 95 per cent were in darkness. This remarkable fact is most clearly seen in Fig. 1 which gives the situation of all the aurora rays from 20° 21°, Greenwich mean time, on Mar. 22, to 2° 53° on the following day. Each ray is marked by a vertical line, and an arrow indicates that the lowest or highest point of the rays were outside the photographic field. The boundary between the dark and sunlit atmosphere is marked by a short stroke the height of which is the mean between the heights corresponding to the highest and lowest measured point of the ray. In this first approximation no account has been taken of refraction.

From this diagram it is clearly seen that the height of the rays is great in the evening and in the morning, but low during the night. The high rays in the

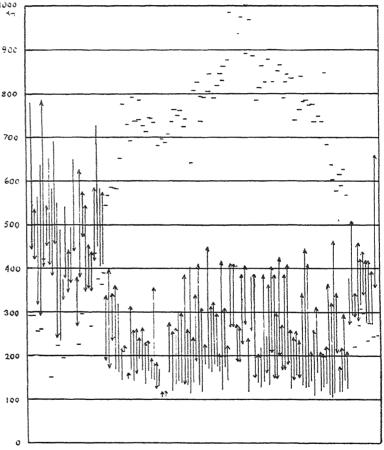

Fig 1

morning of Mar. 23 were of a beautiful blue colour, and through a small pocket spectroscope I saw a quantity of lines in the blue and violet, while the common green aurora line was rather faint. I am sorry that I had used all the plates on the other stations, so that only a very few photograms of these blue rays were taken. But judging from single photographs, the rays later reached heights probably exceeding 800 kilometres.

It seems from these facts that the sunlight has a remarkable action on the upper atmosphere, so that the illumination caused by the electric rays forming the aurora borealis became visible to much greater altitudes than ordinarily.

<sup>&</sup>lt;sup>1</sup> See "Resultats des mesures photogrammétriques des aurores boreales observées dans la Norvege meridunale de 1911 a 1922," Fig. 12, Geofysiske publikationer, vol. 4. No. 7, Oslo, 1926.

It is well known from wireless telegraphy that simhight ionises very strongly the higher atmosphere, and it may be that the accumulated ionising effect of the sunlight and of the electric rays illuminates the atmosphere to a greater altitude than the electric rays alone. Perhaps also the ionisation lifts up the atmosphere by electric charge, as in Vegard's theory, or perhaps such a hiting up may be the effect of a raising of the temperature in those regions. A detailed study of photographs of the spectra of these high rays may solve the question as to the cause of this effect of similable on the altitude of the aurora.

# The Existence of more than one Ionised Layer in the Upper Atmosphere.

During the past year and a half systematic observations have been made at this station on the characteristics of wireless waves deviated by the upper atmosphere. These observations, which have been made as part of the programme of the Radio Research Board of the Department of Scientific and Industrial Research, were begun in collaboration with Mr. M. A. F. Barnett and have more recently been continued with Mr. J. A. Ratcliffe's assistance.

As part of such routine measurements many determinations of the equivalent height of the Kennelly-Heaviside layer have been made, utilising special transmissions from the National Physical Laboratory and from the stations of the British Broadcasting Company. The early summer observations of 1926 showed that the night-time height of this deviating layer, for wave-lengths of 400 metres, was usually 90 km to 130 km. During the period October 1926 – May 1927, however, heights of an entirely different order of magnitude, namely, 250 km. to 350 km., have been frequently measured during the three hours before dawn. On such occasions, after the high values have been recorded for two or three hours, a discontinuity in the series of values occurs 30 to 40 minutes before sumise, and heights of the normal value are again recorded.
